Chapter 269

THE USE OF PROPHYLACTIC MESH IN OPEN AND LAPAROSCOPIC BARIATRIC SURGERY

Montiel Jiménez-Fuertes*

General and Digestive Surgery, Rey Juan Carlos University Hospital, Madrid, Spain

ABSTRACT

Incisional hernia is one of the most common late complications in bariatric surgery. Prophylactic mesh placement is associated with a lower rate of postoperative incisional hernia compared to standard primary closure after open bariatric surgery, without a significant increase in the risk of mesh infection. There are no studies to support the use of prophylactic mesh in laparoscopic bariatric surgery.

Keywords: prophylactic mesh, incisional hernia, bariatric surgery

INTRODUCTION

Incisional hernia is one of the most common complications of abdominal surgery, and bariatric surgery is not an exception. The European Hernia Society (EHS) has developed guidelines on the technique and materials considered more suitable for closing the incisions of the abdominal wall [1]. One of the recommendations is to avoid the use of the middle line incisions. However, the most of the operations are still carried out through these incisions. For the closure of these incisions a continuous suture with slow absorption material is recommended. A large prospective randomized study [2] has confirmed the findings previously published by a Swedish group [3], where it was recommended the use of the technique of small points (small bites) for the closure of laparotomies. Despite this, after 12 months of follow up, 13% of the patients in the study presented an incisional hernia. In patients with risk factors and studies with a more prolonged follow-up, the reported incidence

* Corresponding Author's Email: montiel.jimenez@hospitalreyjuancarlos.es.

of incisional hernia is even higher [4, 5]. These risk factors include obesity, wound infection, aortic aneurysm and oncological surgery.

Surgery for the treatment of incisional hernias presents a high recurrence rate [6], and it is burdened with high social cost and health resources [7]. For all this, the prevention of incisional hernias should be considered a top priority.

To avoid high rates of incisional hernia despite the correct closure of the incision, and especially in high-risk patients, reinforcement of the closure of abdominal wall with a prosthesis has been described [1]. The main factor for the resistance to the adoption of this preventive measure is the infection or other complications related to the use of prosthesis [8]. Basta et al. [9] reported a risk stratification model for incisional hernia (IH) development in bariatric surgery. This was associated with additional readmissions and complications and greater cost and resource utilization. This risk stratification tool identifies candidates for prophylactic mesh, which may optimize outcomes while mitigating the cost. Predictors for IH included open surgical approach (hazard ratio [HR] = 10.3), malnutrition (HR = 3.10), prior abdominal surgery (HR = 2.89), and body mass index $>60\text{kg/m}^2$ (HR = 2.60). Based on these risk factors, patients were stratified into low-, moderate-, and high-risk categories for IH development. Of the high-risk patients, 15.2% developed IH compared with 0.6% of low-risk patients (C-statistic = 0.85).

PROPHYLACTIC MESH IN OPEN BARIATRIC SURGERY

High Body Mass Index (BMI) is a well-known risk factor for the development of postoperative incisional hernia [10], and this problem often needs another operation for its repair, resulting in increased health cost, potential comorbidities and patient dissatisfaction [11]. In high-risk patients undergoing laparotomy, prophylactic mesh has been shown to be more cost-effective than primary closure, with decreased odds of postoperative hernia development in a subanalysis of open bariatric surgery studies [12, 13].

There are only eight studies aimed at the prevention of the development of incisional hernia in open bariatric surgery (Table 1) [8, 14-20]. Surgical Site Infection (SSI) and seroma formation are the most common complications after mesh placement.

A recent systematic review and meta-analysis [21] has shown that the use of prophylactic mesh placement during abdominal wall closure in open bariatric surgery is associated with significantly lower odds of postoperative incisional hernia development compared to standard primary closure.

The standard recommendation for fascial closure is a small bites technique with 4:1 suture length to wound length ratio, but this technique is not the one used in the studies of abdominal wall closure in open bariatric surgery [1]. In this analysis, there were not higher odds of developing SSI or seroma formation with prophylactic mesh, compared to the closure in bariatric surgery without prosthesis [14]. The use of meshes in clean-contaminated surgery raises concerns about an increased risk of infection.

Table 1. Use of prophylactic mesh in open bariatric surgery

Author	Study	N	n with mesh	Mesh position	Mesh	Follow Up (months)	SSI without mesh	SSI with mesh	Incisional Hernia without mesh	Incisional Hernia with mesh	Conclusion
Pans 1998	RCT	288	144	Intraperitoneal	polyglactin	30	5/144	4/144	41/144	33/144	Mesh Not effective

RCT: Randomized controlled trial; CC: control cases; C: Cohorts.

Two of the published studies evaluated biologic meshes, with the idea that wound or mesh infections would be decreased with the use of biologic rather than synthetic mesh [17, 20]. Sarr et al. reported a wound infection rate of 11.9% with the placement of a bioprosthesis compared to 3.6% in the primary closure group ($p > 0.003$) [19]. In contrast, Llaguna et al. found no difference in wound infection rates between the bioprosthesis group compared to the primary closure group (9.09% versus 1.61%, $p = 0.07$) [20]. The comparative efficacy of biologic versus synthetic mesh for prophylaxis against hernia formation in bariatric surgery has not been studied yet, but the results of the meta-analysis [21] suggest that prosthetic mesh, such as polypropylene or polyglactin do not significantly increase the risk for SSI, compared to biologic mesh.

While mesh appears beneficial in preventing incisional hernias, there is no differences in surgical site infection, seroma or wound leakage, but there are only a few studies supporting its routine use, and more quality studies are needed to recommend the use of prophylactic mesh in open bariatric surgery.

PROPHYLACTIC MESH IN LAPAROSCOPIC BARIATRIC SURGERY

Laparoscopic approach has been a revolution in surgery, and bariatric procedures are not an exception. An increasing number of bariatric surgeries are performed laparoscopically. Laparoscopic surgery reduces, but not eliminates, the rate of incisional hernia. One of the problems of this approach is the development of hernias in port-site incisions, and the real incidence is unknown (Table 2). The accepted rate for port-site site hernias is about 3%. Patients undergoing bariatric surgery are more susceptible to suffer from this complication, because the obesity is an increased risk factor and because the bariatric surgery looks for a programmed undernutrition, which has no beneficial effects on the healing of surgical wounds [22].

Table 2. Incidence of trocar site hernia in laparoscopic bariatric surgery

Author	n	Follow up (months)	% IH	Trocar size	Trocar position
Shauer 2000	275	114	0,36	-	-
Johnson 2006	747	20	1,3	10	umbilical
Tuoli 2008	1000	97	0,1	-	-
Hussain 2009	63	43	0	5, 10	

The only classification of port-site hernias is Tonouchi's one (Table 3) [23]. It is accepted that large port-site orifices should be sutures, to prevent herniation, but in morbidly obese patients, the closure of the anterior fascia is very difficult and does not prevent from preperitoneal herniation. Both, the diameter of the port and the mechanism of introduction may have a direct influence on the development of a hernia. Orifices greater than 10 mm have a greater possibility of developing port-site hernias. Most of the authors agree than Hasson

port orifices and those greater than 10 mm should always be closed, but the closure of the fascial defect is very difficult in morbidly obese patients. Different devices and methods have been developed to solve this problem, from the simple utilization of a Reverdin needle to complex instruments designed for advanced laparoscopic surgery.

Table 3. Tonouchi classification for trocar site hernia

	Early-onset tpe	Late-onset type	Special type
Characteristics	Dehiscence of peritoneum, anterior and posterior fascia	Dehiscence of anterior and posterior fascial plane	Dehiscence of all abdominal wall
Interval	A few days	Several months	A few days to 10 d
Main manifestation	Small bowel obstruction	Hernia without small bowel obstruction	Protusion of intestine and omentum
Scheme			

There is no consensus regarding the type of port and when to close the port holes. According to Latyf et al. [24], the use of blade trocars should be avoided, and the expansion ones are recommended, closing the holes over 8 mm, because these ports make less abdominal wall trauma, allowing the reapproximation of the muscles when they are removed. Fascial closure in morbidly obese patients is a hard difficult task, and it does not prevent completely hernia development [25].

Only a total wall closure system the complete cover of the defect is assured, though herniation may happen even after a correct closure. Pilone et al. [26] reported an incidence of assure hernia of 1.6% in patients with laparoscopic bariatric surgery without closure of the ports, with 54 months of follow up. Oblique placement of 12 mm ports allow to consider not closing the holes, minimizing in this way the appearance of hernias at this level. In certain procedures, as in vertical gastrectomy, sometimes it is necessary to expand one of the 12 mm or 15 mm trocars to extract the stomach and it is advisable to close this enlarged trocar to avoid a hernia in this place. In reference to the closure of these 15 mm trocars or 12 mm extended during vertical gastrectomy, some authors have proposed the use of intra-abdominal meshes, with a double objective: on one hand, they reduce the possibility of hernias at this level taking account the difficulties of closing the holes through an anterior approach in the obese, given the great thickness of the adipose tissue they present; and on the other, because by avoiding the closure with transfascial needle under direct vision, the possibilities of existence of pain is decreased, which facilitates the recovery of the patient.

Since the direct closure of the trocar orifices is technically complex and its results are variables, reinforcement has been proposed as a solution with a prosthetic material. These meshes are in most cases of polypropylene with a permanent or absorbable cover, that allows its contact with intra-abdominal viscera. The main problem of these meshes is the fact of leaving an intr-abdominal material, in addition to a potential increase of seromas and infections, and the extra-cost of the procedure. On the other hand, the use of these meshes

also has advantages, such as the reduction of postoperative pain since it prevents closing the holes with tension sutures, especially when this closure is performed with a transmural needle.

There are no randomized control trials, prospective observational studies or retrospective cohort studies using the prophylactic mesh insertion during laparoscopic bariatric surgery. Sánchez Pernaute et al. described the technique of prophylactic insertion of polytetrafluoroethylene (PTFE) mesh at the time of laparoscopic bariatric surgery in 216 patients, reporting a reduction of port site hernia from 3% to 1.3%, and recommended its use in larger diameter orifices in bariatric patients [27]. The mesh easily covers the whole peritoneal defect, preventing also preperitoneal Richter's hernia, and fills the trocar path all through the subcutaneous, fascial and muscular planes with a polypropylene band, which generates an inflammatory local response that should help to prevent future herniations after weight loss. There are no studies evaluating outcomes after prophylactic mesh insertion during laparoscopic bariatric surgery. Randomized control trial studies on mesh prophylaxis for port site incisional hernia are needed.

In addition to the need for more studies on prophylactic mesh in open and laparoscopic bariatric surgery, analysis of the cost-effectiveness of mesh use will also be critical in determining the benefit of changing routine practice to include prophylactic mesh for the closure. Previous cost-analysis on prophylactic mesh use in high-risk abdominal laparotomy patients, not restricted, but including bariatric surgery, found that mesh is more effective, less costly, and overall more cost-effective than standard primary suture closure [28].

Chapter 270

PROPHYLAXIS OF INTERNAL HERNIAS

Manuel Ferrer-Márquez*, MD and Maria José Solvas-Salmerón

Department of Bariatric Surgery, Torrecárdenas Hospital, Almería, Spain

ABSTRACT

Understanding the complications of bariatric surgery is essential for their prevention and reduction of their incidence. Bowel obstruction is the most frequent late complication after gastric bypass, and its consequences can be devastating. The following chapter discusses possible prophylactic measures aimed at preventing the occurrence of this complication.

Keywords: internal hernia, closure of mesenteric defects, non-absorbable suture, small bowel obstruction

1. INTRODUCTION

Complications associated with derivative bariatric techniques may become frequent. Therefore, they should be performed by surgeons experienced in obesity surgery and advanced laparoscopic techniques [1-4]. Among these complications, internal hernias are the most frequent cause of bowel obstruction after bariatric surgery. Knowledge and prevention are essential in order to reduce their occurrence and, consequently, the morbimortality associated with the surgical technique as much as possible.

2. INTERNAL HERNIA AFTER BARIATRIC SURGERY

Internal hernia may be defined as “a defect of unusual size within a body cavity, into which intestines may intrude and become incarcerated or strangulated” [5].

It is currently the most frequent (0.5-12%) late complication after derivative bariatric techniques, and can be life-threatening to patients. Therefore, our knowledge is essential for prevention, early diagnosis and effective treatment [6-8].

It is difficult to know the real incidence of internal hernias since many patients are lost in follow-up, and each group studying this pathology presents different follow-up intervals.

Three anatomical spaces have been described as the possible sites for the internal hernias caused by this surgery [9].

- 1) The mesocolic space, in the entrance orifice for the alimentary limb when it is passed through the mesocolon.
- 2) The Petersen space, between the mesenteric of the alimentary limb and the mesocolon.
- 3) The intermesenteric space behind the jejunojunal anastomosis.

It is important to note that these spaces do not exist in the patient naturally, but rather are created by the surgeon when performing these surgical techniques.

Although any mixed technique can cause this type of complication, gastric bypass is the most studied bariatric technique.

The most common site for internal hernias after a retrocolic gastric bypass is the mesocolic tunnel (transmesocolic hernia), whereas in the case of an antecolic gastric bypass it is the Petersen space [10].

Despite all the advantages of laparoscopic surgery, the rate of internal hernias has increased with the use of these techniques [11]. This seems to be due, on the one hand, to the small amount of adhesions formed by the minimally invasive techniques and, on the other hand, to the fact that many surgeons do not systematically close the defects created after surgery with a non-absorbable running suture.

Figure 1. Spaces created in the retrocolic gastric bypass.

Internal hernias usually appear two years after surgery [12], after the patient has lost weight. This fact appears to be a factor for opening potential spaces in which hernias may occur because of the elongation of the mesentery and the laxity of the mesenteric defect. Occurrence can be acute or chronic. When acute clinical signs are presented, the indication for urgent revisional surgery should not be delayed, as a delay in diagnosis could have fatal consequences for the patient. In the event of chronic clinical condition, the patient usually presents vague symptomatology such as intermittent periumbilical or epigastric abdominal pain, with or without vomiting, probably related to episodes of incarceration and spontaneous resolution of the bowel loops.

A simple abdominal X-ray rarely helps diagnosis; Computed Tomography (CT) with intravenous and enteral contrast appears to be the most useful test for the diagnosis of internal hernias. However, it may occasionally show inconclusive or falsely negative results. Typical signs of internal hernia include mesenteric torsion, dilatation of bowel loops, presence of collections or pneumoperitoneum in advanced cases, and even ischemia. In any case, exploratory laparoscopy is the diagnostic-therapeutic procedure that confirms the findings [13].

Figure 2. Abdominal CT: Dilated jejunal loops with caliber change in relation to possible internal hernia are observed.

3. METHODS OF PROPHYLAXIS IN THE LITERATURE

Understanding the complications of laparoscopic gastric bypass is essential in preventing their occurrence. Over the last few years, different mechanisms aimed at reducing the rate of internal hernias after bariatric surgery have been proposed. To date, however, questions about which technique would lead to better outcomes still remain. Among the issues to consider are the following:

- Antecolic or retrocolic gastrojejunal anastomosis.
- Systematically closed or untreated defects when creating the anastomosis.
- Closure by running suture or loose stitches.
- Use of absorbable or non-absorbable suture.
- Closure by sutures or other suitable means.

In this section, we will try to show what the literature suggests about these issues.

For several years, there has been controversy about how to ascend the Roux-en-Y loop to the stomach (*antecolic or retrocolic*). Proponents of the first approach argue that it is simpler, has less surgical risk, and eliminates the risk of herniation through the mesocolic space. Nevertheless, support for the second variant is based on different features: Given the fact that the route is shorter, the loop has less tension to perform the anastomosis, there is a lower risk of ischemia and bleeding, since the omentum division is not necessary as in the antecolic variant, and it facilitates the revision of the surgery in the future if needed. Several authors have reported a decrease in the internal hernia rate when ascending the loop in an antecolic fashion. Thus, Comeau et al., [14] reported in their series a tendency to reduce the incidence of internal hernias from 6%, using the retrocolic approach, to 3.3% with the antecolic technique ($p < 0.01$). Ahmed et al., [15] concluded, in a series of 2572 patients, that the antecolic variant was associated with a significant reduction in the incidence of internal hernias. A study by Escalona et al also showed a significantly higher internal hernia rate with the retrocolic vs. antecolic technique (9.3% vs 1.8% respectively; $p < 0.0001$), and the retrocolic positioning was identified in the multivariate analysis as a factor for internal hernias ($p < 0.001$) [16]. Other groups reported similar results by modifying the ascending loop from retrocolic to antecolic positioning [17, 18].

The *closure of the defect* has been agreed by many authors as the best way to reduce the incidence of hernias [19-22]. However, it is still at present a subject for debate. It can be a technically difficult process that is not exempt from risks, which increases the overall risk of the surgery. Several authors mention risks such as mesenteric tearing, with consequent hematoma formation or mesenteric vessel damage; the tension of the gastrojejunal or jejunojejunal anastomoses, caused by the sutures; and adhesions, which may cause small bowel obstruction [23].

Some researchers suggest that partial closure of the defect may be even more dangerous than leaving it open, stating that the existence of a small orifice can increase the risk of incarceration. Others, however, argue that, in order not to underestimate the size of the defect, an adequate surgical field exposure (with the bowel and mesentery in a properly aligned fashion) is essential. The closure, therefore, should be performed from the base of the mesentery to the intestinal border, or vice versa.

Champion and Williams [24] were the first to compare closure versus nonclosure of the defect in a long series of patients who underwent gastric bypass with the retrocolic approach, without showing differences in the incidence of internal hernias between both groups (4.1% in the closure group vs 4.7% in the nonclosure group).

In contrast, Carmody et al., [25] reported a significant reduction of internal hernias after retrocolic gastric bypass when using systematic closure (0.6%) compared with nonclosure (7.5%) of the mesenteric defect.

While Rosas et al., [26] failed to show statistically significant differences between two randomized groups (closure vs nonclosure of the defect), the number of patients included in the study was insufficient to enable drawing solid conclusions ($n = 50$ in the closure group vs $n = 55$ in the nonclosure group).

In a recent meta-analysis, which included 45 articles and 31320 patients, the lowest incidence of internal hernias was shown in the group with antecolic variant and closure of all defects (1%; $p < 0.001$), followed by the nonclosure antecolic group and the retrocolic group with closure of the mesenteric and mesocolic defects (both 2%; $p < 0.001$). The authors concluded that an antecolic approach and the closure of both mesenteric and Petersen defects reported the lowest incidence of hernias after gastric bypass [27].

Two clinical trials have been implemented in order to clarify the benefits of the mesenteric closure. The first multicenter clinical trial was conducted in Sweden [28], in which two branches were compared: closure ($n = 1259$) or nonclosure ($n = 1248$) of the mesenteric defect. At 3-year follow-up, the incidence of reintervention due to bowel obstruction was significantly lower in the closure group ($p = 0.0002$). The results show that the closure of mesenteric defects with non-absorbable running suture during laparoscopic gastric bypass significantly reduces the need for reintervention because of bowel obstruction during the three years after surgery. In any case, the closure of the defect was associated in the study with a longer operative time and increased complications in the early postoperative period (mainly by jejunostomy torsion).

The second study of interest is a Danish study (NCT01595230) that is currently enrolling patients. Five hundred patients will be randomized between closure of the intermesenteric defects with staples and leaving the defects open. The primary outcome is internal hernia development after 5 years of follow-up [29].

Regarding the type of closure to be performed, most authors suggest the use of a non-absorbable running suture, arguing that the risk of internal hernia increases over time, and that non-absorbable sutures facilitate the formation of adhesions, which are needed for the closure of the orifices. The use of intermittent stitches presents a higher failure rate, which could be caused by the significant weight loss suffered by these patients and the progressive mesenteric thinning, which may cause the occurrence of small gaps, which over time increase in size and enable the entry of bowel loops [9].

In recent years, barbed sutures have been used more frequently to try to reduce the surgical complications that intracorporeal sutures present, as well as surgical time [30]. In any case, there are no studies regarding the closure of mesenteries that compare this type of suture with conventional ones.

The use of sutures compared to other techniques such as glue or clips is a subject for discussion. While sutures have a higher tensile strength, clips have been tested with promising results. Thus, Aghajani et al support the closure of mesenteries in order to reduce the risk of internal hernias, and propose a simplified method for their closure by using clips [31].

Other factors have been proposed in order to decrease the occurrence of internal hernias: Quebbemann and Dallal suggest that a leftward orientation of the Roux limb in LRYGB will result in a significantly lower rate of internal hernia [32]; Nandipati et al report that the anticlockwise rotation of the Roux limb allowed the jejunojejunostomy to be located on the left side of the abdomen, allowing the jejunojejunostomy to lie in its more natural position on the left side of the mesenteric axis (counterclockwise 0.7% vs clockwise 6.9%; $p = 0.0018$)

[12]. There are other surgical techniques such as nondivision of the jejunal mesentery [33], placement of an antiostruction stitch, and left or right Roux limb configuration.

Understanding the factors that may cause small bowel obstruction after mixed bariatric surgery and performing a precise surgery considering the aforementioned issues will minimize the incidence of this complication, the results of which can be catastrophic.

Chapter 271

EPIDEMIOLOGY OF SURGICAL SITE INFECTION

Pablo Priego*, MD, PhD

Department of General Surgery, Division of Esophagogastric and Bariatric Surgery,
Ramón y Cajal University Hospital, Madrid, Spain

ABSTRACT

Surgical site infection (SSI) refers to an infection that occurs within 30 days after surgery in the part of the body where the surgery took place. These infections may be superficial (involving the skin only) or deep incisional infections or infections involving organs, implanted materials or body spaces. True epidemiology of SSI is difficult to identify due to the heterogeneous nature of these infections. In fact, incidence can change between procedures, hospitals, surgeons and patients. SSIs are the first most frequently reported nosocomial infections, accounting for 30% of such infections among hospitalised patients. Moreover, SSI is implicated in one-third of postoperative deaths and accounts for 8% of all deaths caused by a nosocomial infection. Furthermore, SSI incurs considerable increases in healthcare costs. In most SSIs, the responsible pathogens originate from the patient's endogenous flora. The most commonly isolated organisms in clean surgery are *Staphylococcus aureus*, coagulase negative staphylococci, meanwhile in clean-contaminated or contaminated surgery; the most frequent organisms are *Enterococcus* spp. and *Escherichia coli*.

This review aims at exploring epidemiology, bacteriology and risk factors associated with SSI.

Keywords: epidemiology, surgical site infection, microbiology, risk factors, pathogens

HISTORY

The introduction of anesthetics encouraged more surgery, which inadvertently caused more dangerous patient post-operative infections. The concept of infection was unknown until relatively modern times.

* Corresponding Author's Email: papriego@hotmail.com.

The modern concept of asepsis evolved in the 19th century, when Ignaz Semmelweis showed that hand washing prior to delivery reduced puerperal fever [1]. However, until the pioneering work of Joseph Lister in the 1860s, most physicians believed that chemical damage from exposures to bad air (miasma) was responsible for infections in wounds, and facilities for washing hands or a patient's wounds were not available.

Lister became aware of the work of chemist Louis Pasteur, who showed that rotting and fermentation could occur under anaerobic conditions if micro-organisms were present. Lister experienced spraying carbolic acid on his instruments as an antiseptic, and found that this remarkably reduced the incidence of gangrene and surgical site infections (SSIs). His work was groundbreaking and laid the foundations for a rapid advance in infection control that saw modern antiseptic operating theatres widely used within 50 years [1].

Nowadays, strategies for the prevention of SSIs are based both on reducing the risk of bacterial contamination and on improving the patient's defences against infection. This requires a 'bundle' approach, with attention to multiple patient-related and procedure-related risk factors. Evidence-based guidelines for the prevention of SSIs have been published by the Centers for Disease Control (CDC) [2] and World Health Organisation [3]. However, the development of such guidelines is complicated by the heterogeneous nature of SSIs, which makes it difficult to generalise findings from a study in a specific patient population to a wider setting, and by the fact that the impact of many routine practices (e.g. wearing surgical gloves) cannot be evaluated for ethical or logistic reasons.

DEFINITION

The expression 'surgical site infection' (SSI) was introduced in 1992 in order to replace the previous concept of 'surgical wound infection' [4]. SSI refers to an infection that occurs after surgery in the part of the body where the surgery took place. These infections may be superficial (involving the skin only) or deep incisional infections, or infections involving organs, implanted materials or body spaces (Figure 1).

Figure 1. Classification of SSIs according to the Centers for Disease Control National Nosocomial Infections Surveillance (CDC NNIS) System. Reproduced with permission from Mangram et al. [5].

Criterion	CDC 1988	CDC 1992	SISG	NPS	PHLS
Purulent discharge in or exuding from the wound or observed on direct examination	I		✓	✓	✓
Painful spreading erythema indicative of cellulitis			✓	✓	
Purulent drainage	D	SI/D			
Purulent drainage from a drain placed beneath the fascial layer	D				
Purulent drainage from a drain placed through a stab wound into the organ/space		OS			
Organisms isolated from fluid or tissue from the wound	I	SI			
Organisms isolated from fluid or tissue in the organ/space		OS			
Surgeon/physician diagnosis	I/D	SI/DI/OS			
Surgeon deliberately opens wound, unless wound is culture-negative	I/D	SI/DI			
Wound spontaneously dehisces	D	SI/DI			
Pain	D	SI/DI			
Tenderness	D	DI	✓	✓	
Fever > 38°C	D	DI	✓	✓	
Localized swelling (oedema)		SI	✓	✓	
Redness or extending margin or erythema		SI	✓	✓	
Patient still receiving active treatment for a wound with discharged pus				or ✓	
Heat		SI			
Abscess or other evidence of infection found on direct examination	D	DI/OS			

*Reproduced from reference 4.
 CDC: Centers for Disease Control and Prevention; SISG: Surgical Infection Study Group; NPS: National Prevalence Survey; PHLS: Public Health Laboratory Service.
 CDC 1988 definitions: I, incisional surgical wound infection; D, deep surgical wound infection. CDC 1992 definitions: SI, superficial incisional; DI, deep incisional; OS, organ/space. The SISG and NPS allow fever (>38°C), tenderness, oedema, an extending margin of erythema or if the patient is still receiving treatment for the wound.

Figure 2. Definitions of SSI (Reproduced with permission from Global guidelines for the prevention of surgical site infection. World Health Organization (2016) [3].

SSI is also defined as an infection that occurs within 30 days after the operation and involves the skin and subcutaneous tissue of the incision (superficial incisional) and/or the deep soft tissue (for example, fascia, muscle) of the incision (deep incisional) and/or any part of the anatomy (for example, organs and spaces) other than the incision that was opened or manipulated during an operation (organ/space) [3].

There are many definitions of SSI and a systematic review identified as many as 41 different definitions. However, only five were described as being standardized definitions created by multidisciplinary groups (Figure 2).

The period of surveillance during the first 30 postoperative days or 1 year in case of receiving implants has been modified in the last years by CDC. Currently, it has been established two different kind of classifications regarding procedures and these period of surveillance change from 30 to 90 days in them (Table 1) [6].

Table 1. Period of surveillance for deep or organ/space surgical infection recommended by CDC (2015)

Period of surveillance for deep or organ/space surgical infection recommended by CDC (2015)	
Surveillance of 30 days	Surveillance of 90 days
Aortic aneurysm Amputation of extremity Appendectomy Hepatobiliopancreatic surgery Cholecystectomy Colorectal surgery Gastric surgery Small bowel surgery Neck, thyroid and parathyroid surgery Splenectomy Exploratory laparoscopy Ovarian surgery Abdominal or vaginal hysterectomy Caesarean surgery Kidney, liver and cardiac transplantation Thoracic surgery	Breast surgery Herniorrhaphy Implanting a pacemaker Peripheral vascular surgery Hip and knee prosthesis Spinal surgery Craniotomy Open bone fracture
Superficial SSIs are only controlled for 30 days with independence of type of surgery	

Surgical Wound [3]

Surgical wound refers to a wound created when an incision is made with a scalpel or other sharp cutting device and then closed in the operating room by suture, staple, adhesive tape, or glue and resulting in close approximation to the skin edges.

Surgical wounds are classified according to level of contamination into four classes. This classification allows a better prediction of risk of infections and wound healing outcomes, thus allowing most favorable treatment for each type of surgical wound.

Clean: refers to an uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital or uninfected urinary tracts are not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow non-penetrating (blunt) trauma should be included in this category if they meet the criteria.

Clean-contaminated: refers to operative wounds in which the respiratory, alimentary, genital or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.

Contaminated: refers to open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (for example, open cardiac massage) or gross spillage from the gastrointestinal tract, and incisions in which acute, non-purulent inflammation is encountered, including necrotic tissue without evidence of purulent drainage (for example, dry gangrene), are included in this category.

Dirty or infected: includes old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation.

EPIDEMIOLOGY

SSIs are a common cause of healthcare-associated infection (HAI). True epidemiology of SSI is difficult to identify due to the heterogeneous nature of these infections. In fact, incidence can change between procedures, hospitals, surgeons and patients [7]. Data from the United States and Spain show that SSIs are the first most frequently reported nosocomial infections, accounting for 30% of such infections among hospitalised patients. Furthermore, SSI is a serious complication of surgical procedures that occurs after approximately 2-7% of surgeries. However, its incidence depends on the surgical procedure, the surveillance criteria used, and the quality of data collection.

Moreover, SSI is the most common complication following major gastrointestinal surgery, affecting between 25% and 40% of patients after midline laparotomy (especially in transplantation and surgical oncology) [8]. Fortunately, the increasing use of minimally invasive surgery approach has resulted in a decrease in the incidence of SSIs.

Actually, SSI occurs 17 days after surgery with a range of 6-41 days. In colorectal surgery, 70% of SSI develops after discharge home [9].

Impact of SSIs on Healthcare Resources

SSI is implicated in one-third of postoperative deaths and accounts for 8% of all deaths caused by a nosocomial infection. Furthermore, SSIs cause pain and discomfort, increase hospital stay, require readmission to hospital or intensive care unit (ICU) treatment, and definitively put patients at greater risk of secondary infectious complications [5].

Kirkland et al. [10], reported that the relative risk for death associated with SSIs was 2.2, and those for readmission and ICU treatment were 5.5 and 1.6, respectively. Moreover, patients with SSIs required longer hospitalization (11 vs. 6 days) when compared with uninfected patients, and the median extra duration attributable to SSIs was between 5 to 10 days [11].

As a result, SSIs incur considerable increases in healthcare costs. The hospital-related cost of a single SSI has been estimated at \$12,000–\$35,000 and estimates of annual nationwide hospital costs of SSI have ranged from \$3 billion to \$10 billion [12].

MICROBIOLOGY

In most SSIs, the responsible pathogens originate from the patient's endogenous flora. Type of organisms isolated depends on type of surgery. The most commonly isolated organisms in clean surgery are *Staphylococcus aureus*, coagulase negative staphylococci,

meanwhile in clean-contaminated or contaminated surgery, the most frequent organisms are *Enterococcus* spp. and *Escherichia coli* [13, 14].

Results from EPINE study of Spain in 2013 [15], shows that in gastrointestinal surgery, SSI is secondary to gram-negative germs in 60% and gram-positive cocci in 32%. Most frequent isolated organisms are *Escherichia coli* (28%), *Enterococcus* spp. (15%), *Streptococcus* spp. (8%), *Pseudomonas aeruginosa* (7%), coagulase negative staphylococci (5%), *Staphylococcus aureus* (5%, methicilin-resistant 2%), *Candida* spp. (4%), *Klebsiella* spp. (4%), *Enterobacter* spp. (4%), *Proteus mirabilis* (3%) and *Bacteroides fragilis* (3%) [6].

Nowadays, there are an increase proportion of infections caused by pathogens antimicrobial resistance, like methicilin-resistant *Staphylococcus aureus* (MRSA) or *Candida*. This could be indicative to the increasing number of immunocompromised surgical patients or even severely ill, as well as to the widespread overuse of broad-spectrum antibiotics. This MRSA infection not only is associated with long and expensive hospitalizations but also with high mortality rates.

Less frequent are infections caused by *Serratia marcescens*, *Moxarella osloensis*, *Rhizopus oryzae*, *Clostridium perfringens*, *Rhodococcus bronchialis*, *Nocardia farcinica*, *Legionella pneumophila*, *Legionella dumoffii* and *Pseudomonas multivorans*. However, when these infections are detected, a meticulous epidemiologic investigation must be taking.

Pathogens of concern that cause SSIs may be introduced to the site of wound or surgery via several routes like the patient's endogenous flora or preoperative infection sites remote from the operative, particularly in patients undergoing insertion of a prosthesis or other implant. In addition to the patient's endogenous flora, SSI pathogens may originate from exogenous sources such as members of the surgical team, the operating theatre environment, and instruments and materials brought within the sterile field during the procedure.

The risk of an SSI developing after microbial contamination of the surgical site will depend on the dose and virulence of the pathogen and the patient's level of resistance, according to the relationship

$$\text{Risk of SSI} = \frac{\text{Dose of bacterial contamination} \times \text{virulence}}{\text{Resistance of patient}}$$

The risk of SSI is considered to be significant when organisms in the tissue exceed 105 organisms per gram of tissue, although lower doses may be required if foreign material such as sutures is present. The virulence of the organism relates to its ability to produce toxins or other factors that increase its ability to invade or damage tissue. When the balance between the patient's defense system and the number of pathogenic organisms is disrupted SSIs occur. Mortality rates in patients infected with highly virulent pathogens such as MRSA may be as high as 74% [7].

RISKS FACTORS FOR SSIs

A number of patient-related and procedure-related factors have been shown to influence the risk of SSIs (Table 2). These include patient-related (endogenous factors) and procedure-related (exogenous factors). Some variables are obviously not modifiable, such as age and gender. However, other potential factors can be improved to increase the likelihood of a

positive surgical outcome, such as nutritional status, tobacco use, correct use of antibiotics and the intraoperative technique [7].

The risk of SSI in an individual patient can be estimated using various scoring systems. Culver et al. in 1991 [16], reported the National Nosocomial Infections Surveillance (NNIS) SSI Risk Index. This is the most frequent index in order to calculate the probability of SSI. This index has a range of 0-3, and is calculated by assigning one point for each of three variables (Table 3):

- a) Duration of surgery longer than the approximate 75th percentile of the duration of the specific operation being performed (1 point)
- b) Type of surgery: The presence of a contaminated, dirty or infected, wound (1 point)
- c) Classification of the American Society of Anesthesiologists score: A score of > 3 (i.e., mild systemic disease) is assigned with 1 point.

Table 2. Patient-related and procedure-related factors that may influence the risk of surgical site infections (adapted from Mangram et al.) [5]

Patient-related	Procedure-related
Age	Duration of surgical scrub
Nutritional status	Skin antisepsis
Diabetes	Preoperative shaving
Smoking	Preoperative skin preparation
Obesity	Duration of operation
Coexistent infection at a remote body site	Antimicrobial prophylaxis
Colonisation with micro-organisms (particularly <i>Staphylococcus aureus</i>)	Operating room ventilation
Altered immune response	Inadequate sterilisation of surgical instruments
Length of preoperative hospital stay	Foreign material in the surgical site
	Surgical drains
	Surgical technique
	-poor haemostasis
	-failure to obliterate dead space
	-tissue trauma

Korol et al. [17] performed a systematic review of 57 studies and identify an increased risk of SSI with the following factors: a high body mass index, a severe score according to the US National Nosocomial Infections Surveillance (NNIS) risk Index, severe wound class, diabetes and a prolongation of surgery duration. Furthermore, a metaanalysis of Zhang et al. [18], suggested that diabetes mellitus is significantly associated with an increased risk of SSI. Indeed, in European studies [19], it has also been identified a longer duration of surgery, an American Society of Anesthesiologists score of at least 3 and a pre-surgery hospital stay of at least 2 days as factors associated with an increased risk of SSI, while videoscopic procedures reduced SSI rates.

Recently, a systematic review conducted by WHO [20-33], tried to describe the relationship between surgical volume and the risk of SSI. A moderate quality of evidence showed that surgical procedures performed in high-/medium volume hospitals have lower SSI rates compared to low-volume hospitals (OR: 0.69; 95% CI: 0.55-0.87 and OR: 0.80; 95% CI: 0.69-0.94, respectively). In addition, there was a moderate quality of evidence that surgical procedures performed by high- or medium-volume surgeons have lower SSI rates

(OR: 0.67; 95% CI: 0.55-0.81 and OR: 0.73; 95% CI: 0.63-0.85, respectively) compared to low volume hospitals. However, there was controversial evidence when high- and medium-volume hospitals were compared and it remains unclear whether there is a linear relationship between procedure/surgeon volume and the SSI rate.

Table 3. Estimation of preoperative SSI risk based on the National Nosocomial Infections Surveillance System (NNISS)

Estimation of preoperative SSI risk based on the National Nosocomial Infections Surveillance System (NNISS)			
NNISS			
1- Duration of surgery longer than the approximate 75th percentile of the duration of the specific operation being performed (1 point)			
2-Type of surgery: The presence of a contaminated, dirty or infected, wound (1 point)			
3- ASA score of >3 is assigned with 1 point.			
KEYS			
	ASA I	A normal healthy patient	
	ASA II	A patient with mild systemic disease	
	ASA III	A patient with severe systemic disease	
	ASA IV	A patient with severe systemic disease that is a constant threat to life	
	ASA V	A moribund patient who is not expected to survive without the operation	
	ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes	
T: Cross point for surgery			
Appendectomy		1 hour	
Pancreas, liver and biliar tract surgery		4 hours	
Cholecystectomy		2 hours	
Colon surgery		3 hours	
Gastric surgery		3 hours	
Smallo bowel surgery		3 hours	
Laparotomy		2 hours	
Another procedures in the digestive tract		3 hours	
RISK OF INFECTION

CLASSIFICATION OF THE SEVERITY OF THE SSI: THE ASEPSIS SCORE

Having a valid, reliable and sensitive scoring system to assess the signs and symptoms of SSI can allow prompt treatment as well as evaluation of its management. The ASEPSIS scoring system, derived from cardiac surgery, was the only established referenced scoring system to assess for SSI. The acronym of ASEPSIS is *Additional treatment, Serous discharge, Erythema, Purulent exudates, Separation of deep tissues, Isolation of bacteria and Stay as inpatient prolonged over fourteen days* [34].

ASEPSIS score evaluates the severity of SSI during the first postoperative week assigning points to several factors (antibiotics, drainage of pus, debridement, evisceration, microbiology). This score classifies postoperative infection in five categories (from satisfactory healing to severe infection) and may evaluate daily the score [6] (Table 4).

Table 4. ASEPSIS score

	Proportion of wound affected (%)					
Wound	0	< 20	20-39	40-50	60-79	>80
characteristics						
Serous exudates	0	1	2	3	4	5
Erythema	0	1	2	3	4	5
Purulent exudates	0	2	4	6	8	10
Separation of Deep tissues	0	2	4	6	8	10
Criteria	Points					
Additional treatment						
-Antibiotics	10					
-Drainage of pus under local anesthesia	5					
-Debridement of wound general anesthesia	10					
Serous discharge	Daily 0-5					
Erythema	Daily 0-5					
Purulent exudates	Daily 0-10					
Separation of deep tissues	Daily 0-10					
Isolation of bacteria	10					
Stay as inpatient prolonged over 14 days	5					
Total score	Category of infection					
0-10	Satisfactory healing					
11-20	Disturbance of healing					
21-30	Minor wound infection					
31-40	Moderate wound infection					
>40	Severe wound infection

ABSTRACT

Surgical site infections (SSI) are one of the most commonly reported healthcare-associated infections worldwide and have adverse effects on patient health and hospital resources. There are several risk factors to develop SSI and include malnutrition. A large part of all patients in the hospital are at nutritional risk, the prevalence of malnutrition is up to 50-55%. Due to this high prevalence current recommendations to avoid the hospital burden to SSIs include identify the presence of malnutrition adopting specific nutritional goals to preoperative and postoperative period.

Keywords: surgical site infections, malnutrition, nutritional support

INTRODUCTION

According to the World Health Organization (WHO) healthcare-associated infections are avoidable infections that affect hundreds of millions of people each year worldwide, and surgical site infection (SSI) is the most frequent healthcare-associated infection in low-income countries, affecting up to a third of patients who had surgery. The incidence of SSI is much lower in high-income countries, while urinary tract infection is the most frequent. SSI is still the second most common in Europe and the USA. In low and middle-income countries the incidence rates ranging from 1.2 to 23.6 per 100 surgical procedures and a pooled

* Corresponding Author's Email: andreisarmiento@hotmail.com.

incidence of 11.8%. By contrast, SSI rates vary between 1.2% and 5.2% in developed countries [1, 2].

Surgical site infection (SSI) is defined by the United States Centers for Disease Control and Prevention as infection related to an operative procedure that occurs at or near the surgical incision within 30 days of the procedure or within 90 days if prosthetic material is implanted at surgery [3].

Several risk factors predispose SSI and are known in the literature. Patient and operation characteristics that may influence the risk of surgical site infection development according to the Centers for Disease Control and Prevention guideline. Patient factors include (age, nutritional status, diabetes, smoking, obesity, coexistent infections at a remote body site, colonization with microorganisms, altered immune response length of preoperative stay). Procedure factors include the duration of surgical scrub, skin antisepsis, preoperative shaving, preoperative skin preparation, duration of operation, antimicrobial prophylaxis, operating room ventilation, inadequate sterilization of instruments, foreign material in the surgical site, surgical techniques, surgical drains) [3, 4]. There are other factors influencing patient to develop SSI for example, Hypoalbuminemia [5].

Nowadays, the relationship between nutritional status and the immune system is well known. Malnutrition impairs immune response may make patients highly susceptible to postoperative infections. Hence, patients with malnutrition may suffer a range of poor outcomes including increased risk of death, sepsis and poor wound healing [6, 7]. This chapter summarizes the recent evidence about the identification and intervention of the malnutrition in the surgical patient to avoid surgical site infections.

MALNUTRITION AS A RISK FACTOR

About 20%–50% of all patients in hospitals are found at risk of under-nutrition, depending on the definition, clinical setting, and screening tools. A large part of these patients at nutritional risk when admitted to the hospital, and in most of the patient's malnutrition develops negatively during the hospital stay [6]. The elderly patients and patients suffering from chronic diseases are more exposed to nutritional risk than other patients [7, 8]. Despite three decades of collective development of knowledge, contemporary malnutrition rates do not appear to have reduced significantly [9]. This can be prevented if special attention is paid to the nutritional care of patients.

Malnutrition is characterized by the presence of two or more of the following characteristics: Insufficient energy intake, weight loss, loss of muscle mass, loss of subcutaneous fat, localized or generalized fluid accumulation or decreased functional status [10].

In general, contributors to adult malnutrition have been described in a number of recent studies. Factors identified include inadequate intake, inadequate access to food, increased nutrient requirements associated with complications of the presenting disease or condition, complications that develop during the course of a hospital stay, and/or complications that occur as a result of treatment, declines in mental, sensory, and/or physical function, changes in metabolism and body composition associated with the aging process itself, and any combination of these factors. In addition to personal contributors to undernutrition, a number

of institutional barriers also contribute to undernutrition's incidence and prevalence. These include factors such as a lack of routinely implemented nutrition screening/assessment protocols, failure to recognize undernutrition, failure to provide nutrition intervention to undernourished patients in a timely/coordinated manner, confusion regarding "ownership" of the nutrition screening, assessment, and intervention process, failure to measure or monitor body weight and/or food and nutrient intake, lack of feeding assistance, and low priority given to nutrition status in institutional settings [11, 12].

Clearly, there may be marked variability in the impact of nutrition among patients with different stages of disease, or even different treatments (e.g., chemotherapy, radiotherapy, advanced disease, serious comorbidities, and emergency surgery). However, patients who are malnourished have compromised immunity and are at significantly higher risk for developing SSI. The provision of nutrition support to patients before surgery has been shown to be effective in reducing SSI among surgical colorectal cancer patients [13, 14, 15].

Malnutrition is a major contributor to increased morbidity and mortality, decreased function and quality of life, increased frequency and length of hospital stay, and higher health care costs [16].

NUTRITIONAL SCREENING

Nutrition screening is only the initial step in the identification of patients who are malnourished or at risk to develop. Effective nutritional screening tools should be easy to use, valid and reliable. The screening process should be performed by trained personnel (medical or other health personnel). The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) now mandates that all hospitals conduct nutrition screening within 24 hours of hospital admission [17, 18].

Nutrition assessments may lead to recommendations for improving nutrition status (e.g., some intervention such as change in diet, enteral or parenteral nutrition, or further medical assessment) or a recommendation for re-screening. Unfortunately, nutritional screening and his interventions are inadequate and infrequent. This is reflected in the fact that only 1 in 5 hospitals have formal nutrition screening, also only 1 out of 5 patients receives any preoperative nutrition intervention, therefore is urgently necessary training personnel and implement multidisciplinary teams [19, 20].

In the clinical and research practice BMI (Body mass index) is the most commonly used marker of nutritional status. However, BMI and weight do not alone provide enough information in terms of assessment of nutritional deficit and sarcopenia [21].

There are several tools to nutrition screening with established reliability and validity, each with specific anthropometric and/or diet related criteria measurements, and are appropriate for use in the acute care or medical-surgical adult patient population:

- Nutrition Risk Screening 2002 (NRS-2002)
- Malnutrition Screening Tool (MST)
- Malnutrition Universal Screening Tool (MUST)
- Nutrition Screening Tool (NST)
- PONS (perioperative nutrition screen) score [20]

There is not universal consensus that what tool is the best. however, the European guidelines recommend the Malnutrition Universal Screening Tool (MUST) for the nutritional evaluation of adults in the community; Nutritional Risk Screening 2002 (NRS-2002) for the detection of undernutrition and the risk of its development in hospital settings and Mini-Nutritional Assessment (MNA) for elderly patients in home-care programs, nursing homes and hospitals. No one of before mentioned test except PONS has been specifically designed for use in the perioperative period [22, 23].

The NRS-2002 and Nutrition Risk in Critically ill (NUTRIC) tools are recommended for use in critically ill adult patients due to their ability to account for nutrition status in relation to disease severity [24].

Recently, American Society for Enhanced Recovery (ASER) and Perioperative Quality Initiative (POQI) conducted an extensive literature review and developed and proposed a novel perioperative nutrition screen—the PONS score (perioperative nutrition screen (PONS)). The PONS is a modified version of the Malnutrition Universal Screening Tool (MUST) that has been modified for perioperative use. The PONS determines the presence of nutrition risk based on a patient's BMI, recent changes in weight, reported recent decrease in dietary intake, and preoperative albumin level. In addition, the PONS includes evaluation of preoperative albumin level, as this is a predictor of postoperative complications, including morbidity/mortality [20].

NUTRITIONAL PREOPERATIVE INTERVENTIONS

Nutrition support intervention in patients identified by screening and assessment as at risk for malnutrition or malnourished may improve clinical outcomes. Nutrition intervention in malnourished patients was associated with improved nutrition status, nutrient intake, physical function, and quality of life. In addition, hospital readmissions were reduced. Considering the high prevalence of malnutrition and its repercussions in patient morbidity-mortality and healthcare cost, nutritional screening measures must be included in an integrated nutritional care plan for patients while in the hospital. PONS score has been specifically designed for use in perioperative period is the reason that we recommend to implement this screening tool in surgical patients [6, 19, 20].

- PONS questions for clinic-based perioperative nutrition screening
- Does the patient have a low BMI <18.5 kg/m² (<20 in >65 y of age)?
- Has the patient experienced a weight loss >10% in past 6 months?
- Has the patient had a reduced oral intake by >50% in the past week? (and/or)
- Does the patient have a preoperative serum albumin <3.0 g/dL?

According to the PONS score subdivide patient in two categories:

- Nutrition Pathway in Low Nutrition Risk Perioperative Patients (i.e., PONS < 1 and Albumin [ALB] > 3.0).
Patients should be encouraged to take in healthy high-protein (with high-quality protein sources, such as eggs, fish, and lean meats/dairy) complex carbohydrate-rich

diets preoperatively. However, many patients will not be able to meet optimal suggested perioperative energy goals of 25 kcal/kg/d and 1.5–2 g/kg/d of protein (~1 g/pound of ideal/adjusted body weight) from routine food intake. Thus, we encourage patients to take high-protein ONSs (oral nutritional supplements) or IMN (immunonutrition) during the perioperative period unrelated to nutritional status [20, 25, 26].

- Nutrition Pathway in Patients Found to Be at Nutrition Risk (i.e., PONS > 1 or ALB < 3.0).

In patients found to be at nutrition risk, we recommend high-protein ONS or IMN be given before surgery. This should have a goal of delivering at least 1.2 g/kg/d total of protein. It is the consensus of the group that high-protein ONS should contain >18 g/protein/serving in a balanced formula. A reasonable goal for most patients is 3 high-protein ONS servings per day. Previous data use preoperative ONS demonstrated benefits on the reduction of surgical-site infections in selected weight-losing patients. Again, because many patients do not meet their energy needs from normal food, especially malnourished patients, it is the consensus of this consensus group to encourage the use of high-protein ONS or IMN. As patient compliance with ONS intake (2–3× a day) is essential for benefit, it is vital to emphasize the key role of ONS in preoperative therapy. Further, cost-effectiveness of ONS in hospitalized patients has been shown in a recent large systematic review [27, 28, 29].

In this context, there are some meta-analyses showed that a multiple nutrient-enhanced nutritional formula (arginine, glutamine, omega 3, fatty acids, nucleotides) was associated with significantly reduced SSI incidence compared with a standard formula, both in the RCTs, however the quality of the evidence was rated very low. Regarding the use of nutritional supplements enhanced with a single nutrient (either arginine, glycine, or branched chain amino acids) with standard nutrition, meta-analyses showed no difference in the risk of SSI although the quality of evidence was low. Notwithstanding, WHO recommends that multiple nutrient enhanced formulas can be used to prevent SSIs in adult patients undergoing major surgery, nevertheless some factors could be considered such as resources and product availability should be carefully assessed, particularly in settings with limited resources [30].

In addition, there are some recommendations that could be adopted according to the Perioperative Quality Initiative (POQI) [20, 30].

Is recommended that patients who are screened as being at nutritional risk before major surgery receive preoperative ONSs for a period of at least seven days. This may be achieved with either of the following:

- IMN formulas (containing arginine and fish oil)
- High-protein ONS (2–3× a day, minimum of 18g protein/dose)

Is recommended that for patients who are screened as being at nutritional risk before major surgery, where oral nutrition supplementation via ONS is not possible, that a dietician be consulted and an enteral feeding tube be placed and home EN (enteral nutrition) initiated for a period of at least seven days. If neither oral nutrition supplementation via ONS nor EN

is possible, or when protein/kcal requirement (>50% of recommended intake) cannot be adequately met by ONS/EN, we recommend preoperative PN (parenteral nutrition) to improve outcomes. Is recommend preoperative fasting from midnight be abandoned. Patients undergoing surgery who are considered to have minimal specific risk of aspiration, we encourage unrestricted access to solids for up to 8h before anesthesia and clear fluids for oral intake up to two hours before the induction of anesthesia.

Is recommend a preoperative carbohydrate drink containing at least 45g of carbohydrate to improve insulin sensitivity (except in type I diabetics due to their insulin deficiency state). We suggest that complex carbohydrate (e.g., maltodextrin) be used when available [31].

NUTRITIONAL POSTOPERATIVE INTERVENTIONS

Postoperative nutritional support is vital in maintaining nutritional status during the catabolic postoperative period and underscored by evidence for early and sustained feeding after surgery as part of ERPs (enhanced recovery pathways) protocols [32].

There are some recommendations that could be adopted according to the Perioperative Quality Initiative (POQI) [20].

Is recommend that a high-protein diet (via diet or high-protein ONS) be initiated on the day of surgery in most cases, with exception of patients without bowel in continuity, with bowel ischemia, or persistent bowel obstruction. Traditional “clear liquid” and “full liquid” diets should not be routinely used.

Is recommend reaching an overall protein intake goal is more important than total calorie intake in the postoperative period.

It is recommended standardized protocols for postoperative nutrition support be instituted.

IMN should be considered in all postoperative major abdominal surgical patients for at least 7 days.

In patients who meet criteria for malnutrition, who are not anticipated to meet nutritional goals (>50% of protein/kcal) through oral intake, we recommend early EN or tube feeding within 24 h. Where goals are not met through EN, we recommend early PN, in combination with EN if possible.

Is recommend when using gastric residual volume's as a marker of feeding tolerance, a cutoff of >500 mL should be used before the tube feeds being suspended or tube feed/EN rate reduced.

In patients started on EN and/or PN, we recommend continuation of EN or PN support for patients who are not able to take in at least 60% of their protein/kcal requirements via the oral route.

Is recommend posthospital high-protein ONS in all patients after major surgery to meet both calorie and protein needs, especially in the previously malnourished, elderly and sarcopenic patient.

NUTRITION IN ILL CRITICAL PATIENTS

Nutritional support during critical illness attenuates the metabolic response to stress, prevents oxidative cellular injury, and modulates the immune system. The stress response to critical illness causes wide fluctuation in metabolic rate.

The hyper-catabolic phase can last for 7–10 days and is manifested by an increase in oxygen demands, cardiac output, and carbon dioxide production. Caloric needs may be increased by up to 100% during this phase. The goal is to provide ongoing monitoring and support with high-protein feedings while avoiding overfeeding and underfeeding. Nutritional modulation of the stress response includes early EN (enteral nutrition), appropriate macro-nutrient and micro-nutrient delivery, and glycemic control [33].

Primary goals of nutritional support and care are to: Preserve and maintain lean muscle mass, provide continuous assessment, reassessment, and modification to optimize outcome, monitor the patient for tolerance and complications such as refeeding syndrome, prevent protein energy malnutrition by giving higher protein content while providing adequate total calories; monitor nutrition goals and target achievement rate of >50% within the first week, and prevent accumulation of a caloric deficit. Indirect calorimetry should be used when available or when predictive equations are known to be inaccurate [33].

The Society of Critical Care Medicine and the American Society of Parenteral and Enteral Nutrition (SCCM/ASPEN), the European Society for Clinical Nutrition and Metabolism (ESPEN), the Academy of Nutrition and Dietetics (AND), and the Canadian Clinical Practice Guidelines for Nutritional Support (CCPG) have developed best practice recommendations:

Nutritional support should be initiated early within the first 24–48 hours in critically ill patients. Current EN practice recommendations are: Preferentially feed via the enteral route, initiate EN within 24–48 hours, reduce interruptions of EN for nursing care and bedside procedures to prevent underfeeding, maintain head of bed (HOB) elevation to reduce aspiration risk, accept GRV (Gastric Residual Volume) up to 500 mL before reducing or stopping EN in the absence of clear signs of intolerance, use motility agents to improve tolerance and reduce GRV, and promote post-pyloric feeding tube placement when feasible. Current PN (Parenteral Nutrition) practice recommendations are to: Only use PN when enteral route is not feasible, use PN based on the patient's nutritional risk classification for malnutrition, delay PN up to seven days if the patient is in Nutritional Risk Class I or II, initiate PN early if the patient is in Nutritional Risk Class III or IV, convert to EN as soon as tolerated to reduce the risks associated with PN. Use of trophic or “trickle feeding” and permissive underfeeding may be beneficial [33, 35].

Use of pharmaconutrients and immunonutrition: Omega-3 fatty acids (fish oils) may be beneficial in acute respiratory distress syndrome (ARDS) patients, use high omega-3 fatty acid to omega-6 fatty acid ratios. The use of arginine, glutamine, nucleotides, antioxidants, and probiotics may be beneficial in specific patients. The use of arginine should be avoided in patients with severe sepsis [36].

Chapter 273

PREOPERATIVE BATH AND SHAVE

Cristina Bernabeu Herraiz*, MD
and Lorena Rodríguez Cazalla, MD

Department of General and Digestive Surgery, University Hospital San Juan,
Alicante, Spain

ABSTRACT

Surgical site infection is one of the most common complication in surgery, that increases length of hospital stay and health cost. This chapter is focused on preoperative bath and hair removal. There is neither clear evidence about the benefits to reduce surgical site infection for preoperative showering or bathing with chlorhexidine nor routine hair removal, which should be performed if it is necessary with clippers instead of razors.

Keywords: Surgical site infection, preoperative bath and shower, skin antiseptics, preoperative hair removal

INTRODUCTION

Surgical site infection (SSI) is a major problem for patients undergoing surgery because it increases not only the cost of health care related to a need of antibiotic therapy and a higher length of hospital stay, but also affects patient recovery [1, 2]. Surgeons and health care authorities pay attention to prevent SSI, since up to 60% of them are avoidable applying adequate prevention programs [1-3].

This chapter is focused on preoperative showering or bathing and hair removal.

* Corresponding Author's Email: cristina.bernabeu.h@gmail.com.

PREOPERATIVE BATH

Whole body bathing or showering with soap or skin antiseptics is a widespread practice before surgery to reduce skin resident and transient bacteria. However the most important question is whether preoperative bathing or showering with antiseptics reduce the incidence of SSI in comparison with their potential for harm such as changes in patterns of bacteria resistance, skin hypersensitivity, etc.

Webster and Osborne reviewed randomized clinical trials comparing antiseptic preparation (4% chlorhexidine gluconate) for preoperative bathing or showering with non-antiseptic preparations or no washing over a 26-year period between 1983 and 2009 (seven trials with 10.157 participants). Three trials involving 7.791 patients compared chlorhexidine with placebo did not result in a significant reduction in SSI with a relative risk of 0.91 (0.80 - 1.04). Three trials involving 1.443 patients compared bar soap with chlorhexidine and there was no significant differences with a relative risk of 1.02 (0.57 - 1.84) and three trials of 1.192 patients compared bathing with chlorhexidine with no washing and only one found a significant difference in favour of bathing with chlorhexidine (relative risk 0.36 [0.17 - 0.79]. Authors concluded that this review does not provide clear evidence of benefit for preoperative showering or bathing with chlorhexidine over other wash products to reduce SSI [4]. Smaller studies have not found differences between patients who washed with chlorhexidine and those who did not wash preoperatively [5-7].

Chlebicki *et al.* performed a meta-analysis of sixteen trials involving 17.932 patients, 7.952 received a chlorhexidine bath and 9.980 with others. Chlorhexidine bathing did not significantly reduce overall incidence of SSI when compared with soap, placebo or no shower or bath (relative risk 0.90 [0.77 - 1.05]) [8].

PREOPERATIVE SHAVE

Preparation the patient for surgery has traditionally included the routine hair removal from the incision site because its presence can interfere with the exposure, the suturing and the application of adhesive drapes. However some studies claim that preoperative hair removal is harmful, increase SSI and should be avoided [9, 10].

Hair can be removed by several different ways which include shaving, clipping the hair and using a chemical creams. Shaving is the commonest and cheapest method, it uses a sharp blade, which is drawn over the patient's skin to cut hair close to the surface of the skin. Clippers use fine teeth to cut hair close to the patient's skin, leaving around one millimetre of hair in length. Depilatory creams are chemicals which dissolve the hair itself, but is a slower process, because the cream has to remain in contact with the hair for between five and 20 minutes, that's why there is a risk of irritant or allergic reactions to the cream. During the process of shaving, the skin may experience microscopic cuts and abrasions. It is believed that microorganisms are able to colonize these cuts, thus contaminating the surgical incision site and causing wound infections. That's why clippers they are thought to reduce the risk of cuts and abrasions because do not come into contact with the patient's skin. This hair removal practice can be done everywhere (home, wards, theaters...) but research has suggested, that

hair removal should not take place in the operating theatre as loose hair may contaminate the sterile surgical field [11].

Tanner *et al.* performed a meta-analysis of fourteen trials; six trials compared hair removal (shaving, clipping or depilatory cream) with no hair removal and found no statistically significant difference in SSI rates. Three trials that compared shaving with clipping showed significantly more SSI associated with shaving (relative risk 2.09 [1.15 - 3.80]). Seven trials found no significant difference in SSI rate when hair removal by shaving was compared with depilatory cream (relative risk 1.53 [0.73 - 3.21]). One trial compared two groups that shaved or clipped hair on the day of surgery compared with the day before surgery and there was no statistically significant difference in SSI rate. Authors concluded that there was no significant differences between hair removal and not hair removal; however, when it is necessary to remove hair, the evidence suggests that clippers are associated with fewer SSI than razors [9].

Lefebvre *et al.* performed a meta-analysis of nineteen randomized controlled trials and they described no significant differences between the absence of hair removal and chemical depilation (relative risk 1.05 [0.55 - 2.00]) or clipping (relative risk 0.97 [0.51 - 1.82]) as well as a higher significantly risk of SSI when shaving is used for hair removal in comparison with clipping (relative risk 0.55 [0.38 - 0.79], chemical depilation (relative risk 0.60 [0.36 - 0.97]) or no depilation (relative risk 0.56 [0.34 - 0.96]) [12].

Kowalski *et al.* conducted a single-center randomized clinical trial, 834 patients to clipped group and 844 to not-clipped group. The overall rate of SSI in the per-protocol analysis was 6.12% in clipped group and 6.32% in not-clipped group (absolute risk difference -0.20 [-2.61 to 2.21%]). Authors concluded that SSI rate was similar between hair removal by clipping or not in patients undergoing general surgical procedures [13].

Chapter 274

MECHANICAL BOWEL PREPARATION

Andrés García Marín¹ and Mercedes Pérez López²

¹Department of General and Digestive Surgery, Hospital Hellín, Albacete, Spain

²Department of Nursery, Alicante, Spain

ABSTRACT

The chapter summarizes the recent evidence about the role of mechanical bowel preparation in combination with oral antibiotic prophylaxis in comparison with No Preparation or mechanical bowel preparation alone in the prevention of postoperative morbidity, surgical site infection, anastomotic leakage and ileus, mortality rate and *Clostridium difficile* infection.

Keywords: mechanical bowel preparation, oral antibiotic prophylaxis, surgical site infection, anastomotic leakage, ileus, colorectal surgery, mortality

INTRODUCTION

Surgical site infection (SSI) is a major problem for patients undergoing colorectal surgery (CRS) because it increases not only the cost of health care related to a need of antibiotic therapy and a higher length of hospital stay, but also affects patient recovery and survival [1-3].

Mechanical bowel preparation (MBP) and oral antibiotic prophylaxis (OAP) are specific strategies to prevent SSI in CRS.

MBP defined as oral preparations prior to surgery to clear out solid stool has been studied in randomized controlled trials (RCT). Rollins et al. concluded in a recent meta-analysis of 36 RCT that MBP does not impact in postoperative morbidity and mortality, as well as it produces fluid and electrolyte disturbances and patient dissatisfaction [2, 4].

In fact, Enhanced Recovery After Surgery Society and the American Society for Enhanced Recovery do not recommend the use of MBP without OAP before elective CRS [5, 6].

OAP with nonabsorbable luminal antibiotics, mainly the combination of an aminoglycoside (neomycin or kanamycin) with erythromycin or metronidazole, was firstly proposed in 1971 by Rosenberg and Nichols [7, 8].

Table 1. Comparison between MBP + OAP and MBP alone, No Preparation and OAP [2]

	Studies	RR (95% CI)
30-day mortality		
MBP + OAP vs MBP	17 (14 RCT and 3 CS)	0.58 (0.44-0.76)
MBP + OAP vs No Preparation	2 CS	0.36 (0.17-0.76)
MBP + OAP vs OAP	3 (2 RCT and 1 CS)	0.58 (0.34-0.97)

CS: Cohort Studies. MBP: Mechanical Bowel Preparation. OAP: Oral Antibiotic Prophylaxis. RCT: Randomized Clinical Trial. RR (95% CI): relative risk (95% confidence interval).

RECENT EVIDENCE

Overall, the combination of MBP + OAP is associated with a significant reduction in global morbidity, SSI, anastomotic leakage, postoperative ileus and 30-day mortality in comparison with MBP alone, No Preparation and OAP alone [1, 2, 9-14].

A summary of the evidence related to 30-day mortality is presented in table 1, and related to SSI (table 2), anastomotic leakage (AL) and postoperative ileus in table 3.

The value of different regimens of oral antibiotics is being evaluated. McSorley et al. conducted a meta-analysis and they concluded that there was a similarly significant effect on SSI with the use of a combination of aminoglycoside and erythromycin (OR 0.40 [0.25 - 0.64]) or aminoglycoside and metronidazole (OR 0.51 [0.39 - 0.68]) [1].

Evidence about *Clostridium difficile* infection was enough for the comparison between MBP + OAP versus MBP in 14 studies (10 RCT and 4 cohort studies), without significant differences (RR 0.94 [0.55 - 1.61]) [2].

Table 2. Comparison between MBP + OAP and MBP alone, NP and OAP [2]

	Studies	RR (95% CI)
SSI		
MBP + OAP vs MBP	35 (26 RCT and 9 CS)	0.51 (0.46-0.56)
MBP + OAP vs NP	4 CS	0.54 (0.43-0.68)
MBP + OAP vs OAP	4 (2 RCT and 2 CS)	0.98 (0.64-1.50)
MBP + OAP vs MBP in laparoscopic vs open approach	Open: 19 RCT. Laparoscopic: 2 RCT	Open: 0.55 (0.44-0.69) Laparoscopic: 0.74 (0.43-1.29)

CS: Cohort Studies. MBP: Mechanical Bowel Preparation. NP: No Preparation. OAP: Oral Antibiotic Prophylaxis. RCT: Randomized Clinical Trial. RR (95% CI): relative risk (95% confidence interval). SSI: Surgical Site Infection.

Table 3. Comparison between MBP + OAP and MBP alone, NP and OAP [2]

AL		
MBP + OAP vs MBP	22 (17 RCT and 5 CS)	0.62 (0.55-0.70)
MBP + OAP vs NP	2 CS	0.52 (0.45-0.59)
MBP + OAP vs OAP	3 (2 RCT and 1 CS)	0.79 (0.59-1.05)
MBP + OAP vs MBP in laparoscopic vs open approach	Open: 9 RCT. Laparoscopic: 2 RCT	Open: 0.69 (0.30-1.60) Laparoscopic: 0.68 (0.28-1.65)
Ileus		
MBP + OAP vs MBP	5 (2 RCT and 3 CS)	0.72 (0.52-0.98)
MBP + OAP vs NP	2 CS	0.72 (0.68-0.77)
MBP + OAP vs OAP	3 (2 RCT + 1 CS)	0.83 (0.73-0.95)
Overall morbidity		
MBP + OAP vs MBP	6 (4 RCT + 2 CS)	0.67 (0.63-0.71)

AL: Anastomotic Leakage. CS: Cohort Studies. MBP: Mechanical Bowel Preparation. NP: No Preparation. OAP: Oral Antibiotic Prophylaxis. RCT: Randomized Clinical Trial. RR (95% CI): relative risk (95% confidence interval).

CONCLUSION

The combination of MBP and OAP was associated with a significant reduction in overall morbidity, SSI, AL, ileus and 30-day mortality in comparison with MBP alone and No Preparation and only in ileus and 30-day mortality in comparison with OAP alone. However, there was not significant differences in *Clostridium difficile* infection.

Chapter 275

ANTIBIOTIC PROPHYLAXIS

Noel Rojas-Bonet^{1,*} and Maria del Mar García-Navarro²

¹Department of General and Digestive Surgery, University Hospital San Juan,
Alicante, Spain

²Department of Internal Medicine, University General Hospital of Alicante,
Alicante, Spain

ABSTRACT

The chapter summarizes the recent evidence about microbiology, indications, recommended antibiotics, timing and dosages in patients undergoing general and digestive procedures.

Keywords: antibiotic prophylaxis, surgical site infection

INTRODUCTION

Surgical site infections (SSI) is defined as infection related to a surgical procedure that occurs within 30 days of the procedure or withing 90 days if prosthetic material is implanted at surgery, which may be incisional (superficial or deep) or organ/space [1].

The goal of antimicrobial prophylaxis is to control bacterial burden, maintaining antibiotic levels above the minimum inhibitory concentration throughout the surgical procedure in order to reduce the risk of infection [1].

EPIDEMIOLOGY

The estimated incidence of SSI ranges from 1% in minimally invasive surgery to 5% in invasive surgery. However, this percentage is probably underestimated, as up to 50% of post-surgical infections occur after discharge [2, 3].

* Corresponding Author's Email: noel.rojas@goumh.umh.es.

The severity of surgical site infections depends on many factors: type of surgery, surgical technique, bacterial inoculum, responsible organism (as well as mono or polymicrobial) and patient characteristics and comorbidities.

Patient risk factors (modifiable and non-modifiable) can contribute to the development of infections and complications [3].

Risk factors whose presence have been directly related to torpid evolution and higher infection rates of the surgical site are those conferring greater difficulty in healing and therefore will increase the period of vulnerability for the appearance of superinfections: age, smoking, the nutritional status, the immunosuppression both intrinsic (primary immunodeficiency, HIV, cancer...) and extrinsic (corticoids, chemotherapy) that hinders the adequate inflammatory response and the defense against the potential risk of infections, diabetes, obesity, peripheral edema and immobilization [4].

Thus, a relationship is found between the comorbidities of the patients and the prevalence of SSI after invasive surgery (ASA I 1.7%, ASA II 4.1%, ASA III 7.3%, ASA IV 7.9%, ASA V 14.3%) [3, 4].

MICROBIOLOGY

The main involved microorganisms in SSI are those found in the skin, mainly grampositive cocci (*Staphylococcus spp.*, *Streptococcus spp.* and, less frequently, *Enterococcus spp.*) and those found in abdominal cavity, mainly gram-negative bacilli (*Escherichia coli*, *Proteus spp.*, *Klebsiella spp.*) and anaerobes (*Bacteroides spp.*) [1].

GENERAL PRINCIPLES OF ANTIBIOTIC PROPHYLAXIS

General principles are intravenous administration and selection of adequate antibiotic with correct posology.

The antibiotic should present a narrow spectrum to cover the typical microorganisms, bactericidal activity, extended half life, good tissue distribution and low adverse effects including a low rate of *Clostridium difficile* infection. According to this, the recommended antibiotic for surgeries above the duodenum in abdominal cavity, neck and breast surgeries would be cefazolin and, in patients with β -lactam allergies, vancomycin and gentamicin, clindamycin and gentamicin or levofloxacin whereas for surgeries below the duodenum, amoxicillin-clavulanic acid, in patients with β -lactam allergies, moxifloxacin, levofloxacin and metronidazole or gentamicin and metronidazole are preferred.

The administration should be performed 30-60 minutes before the start of the procedure; if it is administered more than 120 minutes before, the risk of infection is double that if it is administered in the 120 minutes prior to surgery. If the administration is delayed until after the surgical initiation, the risk of infection is multiplied by 5 [1, 3, 5-9].

Intraoperative redosing is recommended when bleeding greater than 1500 milliliters occurs or surgical procedure lasts more than two half-life of the antibiotic, only for amoxicillin-clavulanic acid at 2-3 hours, cefazolin at 4 hours and clindamycin at 6 hours. Intraoperative redosing is not required for gentamicin / tobramycin, metronidazole and

vancomycin [3, 5-9]. Classical administration with redosing is controversial. In fact, Kirby et al. conducted a colorectal study comparing standard bolus-dosed antibiotic with continuous administration throughout surgery monitoring serum antibiotic concentrations and they showed that the rates of SSI were lower with continuous administration [10].

Postoperative redosing in clean and clean-contaminated surgeries is not recommended with high level of evidence once the surgical incision has been closed, even if drainage is required [3, 6, 8].

Dosing adjustment should be performed according to the patient comorbidities and weight, since the alteration in body composition in obese patients involves a higher risk of erroneous dosing and, therefore, a possible therapeutic failure or toxicity [1, 11, 12]:

- Cefazolin and amoxicillin-clavulanic acid (80 - 160kg): 2gr. Patients lower than 80kg. 1gr., whereas the dosage in patients higher than 160kg is controversial (same or high dose of 3 - 4gr).
- Cefuroxime (> 80kg): 3gr. Patients lower than 80kg. 1.5g.
- Gentamicin: 5 - 7mg/kg.
- Vancomycin: 15mg/kg, with maximum dose of 2gr.
- Clindamycin: 600 – 900. In patient with body mass index higher than 50 kg/m², a high dose of 900 – 1200 is recommended.
- Metronidazole: 15mg/kg.

INDICATIONS

Indications for antibiotic prophylaxis are controversial, depending on the type of surgery. Antibiotic prophylaxis is not always needed for clean surgery since the rate of SSI is very low; it should only be administered in some patients such as oncological and plastic breast surgery, intravascular devices placement, splenectomy in immunosuppression situations and mesh surgery in high risk patients [13-15]. Antibiotic prophylaxis is always needed in clean-contaminated and contaminated procedures; however, it is still unclear in elective laparoscopic cholecystectomy in low-risk patients, considering high risk patients immunosuppressive therapy or disease, ASA $\geq$ III, acute or chronic cholecystitis 6 weeks before surgery, open conversion surgery or intraoperative rupture of the gallbladder [17-19].

Chapter 276

HANDS AND SKIN PREPARATION

Lorena Rodríguez Cazalla* and Cristina Bernabeu Herraiz

Department of General and Digestive Surgery, University Hospital San Juan,
Alicante, Spain

ABSTRACT

Surgical site infection is one of the most frequent complications in abdominal surgery. Hands hygiene and surgical site skin preparation are measures to prevent it. The common techniques are hand scrubbing and hand rubbing, but there is no firm evidence that one type is better than another. Skin preparation is a standard of care that must always be carried out before any invasive procedure and should include an alcohol-based antiseptic agent.

Keywords: surgical site infection, prevention, surgical hand antisepsis, hand hygiene, surgical skin preparation, antiseptic

INTRODUCTION

Surgical site infection (SSI) is one of the most frequent complications in abdominal surgery. It represents one of the most important clinical and economic problems for healthcare systems. This complication is associated with longer hospital stay, the decrease in patient's quality of life and the increase in morbidity, mortality and health costs. Currently, SSI represents in the United States of America around 22% of nosocomial infections [1, 2].

There are many different points in the care pathway where prevention of SSI can take place. This includes antiseptic cleansing of the hands for those who are operating on the patient and also the preparation of the patient's skin. This chapter focuses on these two procedures.

SURGICAL HAND PREPARATION

Historically, hands hygiene has been considered a measure of personal care. However, the relationship between hand washing and the spread of the disease was established in the 19th century thanks to the studies of *Semmelweis* in Vienna and *Holmes* in Boston, who established that hospital-acquired infections are transmitted through the hands of health personnel [3]. Currently, hands hygiene is considered one of the most important measures to prevent the spread of pathogens in healthcare settings [4].

The objective of the surgical hand preparation is to decrease the release of skin bacteria from the hands of the surgical team and to avoid contamination of the surgical field, especially in the case of unnoticed rupture of the sterile glove during the procedure, since the surgical glove is the most important barrier for the migration of microorganisms between the hands of the surgical team and the patient [5, 6]. However, 18% (range: 5-82%) of sterile gloves present perforations after surgery, and over 80% of the cases these perforations are unnoticed by the surgeon. After two hours of surgery, 35% of sterile gloves showed puncture [7].

Surgical hand antisepsis is perhaps the oldest preventative measure used to decrease the incidence of SSI and whose technique has changed most in recent years; for example, during the 19th and 20th century the friction of the skin with a brush was very important but nowadays this practice is totally discouraged due to the skin damages that produces (it is recommended that the friction will be done with the palm of the hand or with a soapy sponge for a single use) [8].

Leclair in 1990 defined antiseptic as “a chemical agent that reduces the microbial population on the skin” [9]. The ideal antiseptic is one that significantly decreases the number of microorganisms in contact with the skin, has broad spectrum, acts quickly with lasting effect, does not produce skin irritation or toxicity and its repeated use is safe [10]. At present, there are several available antiseptic agents, such as:

- Alcohols (60-95%): broad spectrum, fast speed of action, no persistent activity, flammable.
- Chlorhexidine (0.5-4%): broad spectrum, intermediate speed of action, persistent activity, good tolerability, may damage inner ear, eyes and nerve tissue.
- Iodophors (0.5-10%): broad spectrum, intermediate speed of action, decreased effectiveness on contact with organic material, skin irritant, contraindicated in pregnant women, babies and during lactation.
- Phenol derivates (0.5-4%): slow speed of action, no persistent activity, activity neutralized by non-ionic surfactants.
- Triclosan (0.1-2%): no action against viruses and fungi, intermediate speed of action, persistent activity.

Surgical Hand Scrubbing

Surgical hand scrubbing is defined by antisepsis with water and aqueous solution. The most common solutions used for surgical hand scrubbing are chlorhexidine gluconate and povidone iodine.

The application technique, according to World Health Association (WHO), consists of: 1. Scrub each side of each finger, between the fingers, and the back and front of the hand for 2 minutes; 2. Scrub the arms, keeping the hand higher than the arm for all time, wash each side of the arm from the wrist to the elbow for 1 minute; 3. Repeat the process on the other hand and arm; 4. Rinse hands and arms by passing them through the water from fingertips to elbow; 5. Dry hands and arms with sterile towel [12].

Surgical Hand Rubbing

Surgical hand rubbing is defined by antisepsis with alcohol-based solutions, also called waterless scrub.

The application technique, according to the WHO, has a duration of 2 minutes and consists of: 1. Apply 5 ml of solution in the palm of the left hand; 2. Introduce the fingers of the right hand into the solution; 3. Extend the rest of the solution by the right hand upwards reaching the elbow; 4. Apply 5 ml of solution on the right palm and repeat steps 2, 3 and 4 with the left hand and arm; 5. Apply 5 ml more on the left palm by rubbing the solution between the fingers of both hands until the wrists [12].

Recommendations

The Association for Perioperative Practice (AfPP 2011) recommends a prewash with soap and water prior to the first antisepsis of the day to remove dirt (organic material). Most guidelines forbid the use of jewelry, watches or artificial nails in the surgical team's hands [13].

In 2016, Tanner et al. performed a review of four studies about the effect of hand antisepsis in the prevention of SSI and they concluded that there is no strong evidence about the best hand antisepsis. It seems that chlorhexidine reduces the bacterial load on hands more than povidone iodine, but less than the compounds combined with alcohol [9].

Benedetta et al., reviewed six studies (three randomized clinical trials and three observational studies) that compared hand rubbing with hand scrubbing without significant differences related to the incidence of SSI [14].

The WHO recommends that surgical hand preparation be done either by scrubbing with a suitable antimicrobial soap and water or using an alcohol-based hand rub before donning sterile gloves (*strong recommendation, moderate quality of evidence*) [14].

SURGICAL SKIN PREPARATION

The goal of surgical site skin preparation with antiseptics is to reduce the microbial load of the skin before incision and, therefore, decreasing the incidence of SSI [14]. Decontamination of the skin is a standard of care that must always be carried out before any invasive procedure [15, 16].

The three agents mostly used in the surgical site skin preparation are chlorhexidine gluconate, povidone iodine and alcohols, although there are many more available options [4, 15].

The alcoholic compounds are the most microbiologically active agents, but its antimicrobial effect disappears after a few minutes, are inflammable and contraindicated on mucose membranes. Its use for surgical preparation has therefore been practically discontinued. Antiseptics such as chlorhexidine gluconate and povidone iodine are less active than alcohol, but have a greater residual effect. Both can be found in aqueous or alcoholic solutions, the latter being more effective [17].

There are several randomized clinical trials that have compared chlorhexidine-based antiseptics with iodine-based antiseptics in the preoperative preparation of the skin. Most of them have been underpowered to detect differences in SSI rates [18]. Benedetta et al. performed a meta-analysis of twelve randomized clinical trials and they concluded that alcohol-based antiseptics solutions were more effective than aqueous solutions in reducing the risk of SSI (combined OR 0.60 [0.45-0.78]). More specifically, a decrease in SSI risk was observed when comparing the use of alcoholic chlorhexidine with aqueous povidone iodine (combined OR 0.65 [0.47-0.90]) [14]. However, it is important to bear in mind that these studies are comparing two antiseptics combined (chlorhexidine and alcohol) against just one (povidone iodine), attributing the disinfecting power to chlorhexidine and forgetting the role of alcohol [19]. A recent clinical trial showed that the use of alcoholic chlorhexidine for preoperative skin antisepsis at cesarean delivery was associated with a significantly lower risk of SSI than was the use of iodine–alcohol [20].

The recommendations of the main scientific societies are:

- *NICE (2013)*: prepare the skin at the surgical site immediately before incision using an antiseptic (aqueous or alcohol-based) preparation, povidone-iodine or chlorhexidine are most suitable [21].
- *Cochrane (2015)*: preoperative skin preparation with 0.5% chlorhexidine in methylated spirits was associated with lower rates of SSIs following clean surgery than alcohol-based povidone iodine [10].
- *WHO (2016)*: the panel recommends alcohol-based antiseptic solutions that are based on chlorhexidine gluconate for surgical site skin preparation (*strong recommendation; low to moderate quality of evidence*) [14].
- *CDC (2017)*: perform skin preparation with an alcohol-based antiseptic agent unless contraindicated (*strong recommendation; high-quality evidence*) [22].

The antiseptic agent must be applied with a specific applicator or sterile capsule, clamp and gauze, brushing the skin with forward and backward movements. The application must be carried out for about 30 seconds, allowing the product to dry for at least 2 minutes [23].

Chapter 277

HYPEROXYGENATION, HYPOTHERMIA PREVENTION, NORMOGLYCEMIA AND NORMOVOLEMIA

Esther García Villabona*, MD and Carmen Vallejo Lantero, MD

Anesthesiology Department, Hospital Universitario de La Princesa,
Madrid, Spain

ABSTRACT

Surgical site infections (SSIs) are defined as infections anatomically associated with a surgical procedure performed in an operating room and not present prior to the operation. They have been shown to account for up to 16% of healthcare-associated infections. The rate of surgical site infection varies depending on the type of procedure, with rates of less than 1% for orthopaedic procedures and rates of over 10% for large bowel surgery. They can often be prevented with appropriate care before, during and after surgery. [1]

Keywords: surgical site infection, oxygenation, temperature, normovolemia, hiperglycemia.

INTRODUCTION

Surgical site infection (SSI) is a type of healthcare-associated infection in which a surgical incision site becomes infected after a surgical procedure. These infections represent an important problem for patients and a significant financial burden for the health care system. [2]

Many factors in the patient's journey through surgery have been identified as contributing to the risk of SSI. Therefore, the prevention of these infections is complex and requires the integration of a range of preventive measures before, during and after surgery.

There is evidence that optimizing blood flow to the surgical incision, we can decrease surgical site infection rates through the avoidance of hypothermia, hypoxia and decreased

* Corresponding Author's Email: esthergarcivillabona@gmail.com.

perfusion. If an infection does develop, appropriate treatment will minimise morbidity resulting from the infection.

Ideally, perioperative fluid therapy prevents tissue hypoxia by maximizing the cardiac output and thus improving arterial oxygenation. Nevertheless, an adequate assessment of normovolemia remains complicated.

On the other hand, several observational studies showed that hyperglycaemia is associated with an increased risk of SSI in both diabetic and non-diabetic patients. Conflicting results have been reported about the optimal target levels of blood glucose and the ideal timing for glucose control (intra- and/or postoperative).

METHODS

Hyperoxygenation

It has been claimed that patients undergoing surgery with general anesthesia could benefit from a higher than normal inspired oxygen fraction (FiO₂). Some authors have suggested that a high FiO₂ is a simple, inexpensive, and low risk intervention, and that the broader use of this technique should be encouraged in patients undergoing major abdominal procedures. [3]

Several trials have been published on the use of high fractions of inspired oxygen concentration (FiO₂) during the perioperative period and the potential association with lower rates of SSI. This intervention consists of providing patients with 80% oxygen compared to the usual administration of 30% oxygen. Patients are routinely given 100% oxygen for 30 seconds to 2 minutes prior to intubation and then maintained on either “normoxia,” defined as oxygen at FiO₂ 30% or 35%, or “hyperoxia,” defined as oxygen at FiO₂ 80%.

The arguments for providing oxygen levels beyond the standard 30% are largely based on two notions. The first is that the surgical incision may not be adequately perfused and might receive substantially higher oxygen if there is a higher partial pressure of oxygen in the blood. The other concept is that host defense systems might be further improved by higher oxygen partial pressures, particularly by enhancing neutrophil oxidative killing. This argument devolves down to the affinity of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase for oxygen. The Michaelis constant for the enzyme for oxygen is 5-20 μ M Hg O₂. It has been shown that oxygen tension at infected sites is greatly reduced compared with most uninfected tissues (P_{O2} approximating 25 mM of oxygen $\approx$ 3% oxygen). [1]

Overall, it has been shown (with a moderate quality of evidence) that increased perioperative FiO₂ (80%) is beneficial in reducing SSI when compared to standard perioperative FiO₂ (30-35%) in patients undergoing surgical procedures under general anaesthesia with endotracheal intubation. The benefit of hyperoxygenation tended to be greater in open colorectal surgery than in other types of abdominal surgery. Many authors have considered that subgroup as the most likely to profit from a high FiO₂. The question then is, whether this benefit is of clinical relevance. Although the degree of antiinfective efficacy of high FiO₂ seems weak and perhaps disappointing, it seems to be similar to conventional antibiotic prophylaxis in many surgical settings. As most patients in these trials had received prophylactic antibiotics, we may conclude on the efficacy of high FiO₂ as a supplemental antiinfection strategy only. It would be difficult to test the efficacy of high FiO₂

alone from an ethical perspective because the administration of prophylactic antibiotics is widely considered as a standard of care. [3]

Potential Harms

Some authors are cautious about the use of increased FiO₂. Skepticism has been partly related to the fact that high FiO₂ may have deleterious effects on the airways. One hundred percent oxygen at induction or at the end of general anesthesia has been suggested to promote atelectasis over a few minutes, and to cause alteration in gas exchange.

However, this increase in atelectasis has been described after the administration of 100% FiO₂ compared to 80% FiO₂ and showed a meaningful difference between the two concentrations. Moreover, none of the clinical trials investigating the administration of 80% FiO₂ that reported adverse events showed a significant difference in pulmonary complications or other adverse events.

Patients with chronic obstructive pulmonary disease should be evaluated preoperatively and their perioperative anesthesia needs to be designed to minimize complications as the risks of high inspiratory concentrations of oxygen may outweigh the benefits for these patients. [3]

Hypothermia Prevention

Hypothermia is defined as a core temperature below 36°C and is common during and after major surgical procedures lasting more than 2 hours. The human body has a central compartment comprising the major organs where temperature is tightly regulated, and a peripheral compartment where temperature varies widely. Heat loss is compensated by reducing blood flow through the skin and increasing heat production, mainly by inducing muscular activity (shivering) and increasing the basal metabolic rate. Typically, the periphery compartment may be 2°C to 4°C cooler than the core compartment. [4]

Causes of Hypothermia

The most common events leading to hypothermia are the exposure to a cold operating room environment and the anaesthetic-induced impairment of thermoregulatory control.

- Skin surface exposure during the perioperative period can increase heat loss. In addition, cool intravenous and irrigation fluids directly cool patients.
- Sedatives and anaesthetic agents inhibit the normal response to cold, resulting in an improved blood flow to the periphery and increased heat loss.

During the early period of anaesthesia, these effects are seen as a rapid decrease in core temperature caused by redistribution of heat from the central to the peripheral compartment. This early decrease is followed by a more gradual decline, reflecting ongoing heat loss. With epidural or spinal analgesia, the peripheral blockade of vasoconstriction below the level of the nerve block results in vasodilatation and greater ongoing heat loss.

Complications of Hypothermia

Inadvertent non-therapeutic hypothermia is considered to be an adverse effect of general and regional anaesthesia and can cause different complications.

- a) Cardiac complications are the principal cause of morbidity during the postoperative phase because of the release of noradrenaline causing peripheral vasoconstriction and hypertension.
- b) Prolonged recovery from anaesthesia and a longer length of hospital stay.
- c) Even moderate hypothermia (35°C) can alter physiological coagulation mechanisms by affecting platelet function and modifying enzymatic reactions. Decreased platelet activity results in increased bleeding and a greater need for transfusion.
- d) Moderate hypothermia can also reduce the metabolic rate, manifesting as a prolonged effect of certain drugs used during anaesthesia and some uncertainty about their effects. This is particularly significant for elderly patients.
- e) The maintenance of normothermia might reduce the incidence of surgical site infection, but all available studies in this field measure core and not peripheral temperature. The reported lower core temperatures result in a reduced cutaneous temperature at the operative site. Recent health care bundles and guidelines for SSI prevention recommend that body temperature should be maintained above 35.5-36°C during the perioperative period. [1]

Recommended Measures to Prevent Hypothermia

1. Perioperative care:

- Patients, relatives and carers should be informed that staying warm before surgery will lower the risk of postoperative complications.
- When using any temperature recording or warming device, healthcare professionals should be trained in their use.
- Measure the patient's temperature using a site that produces either: a direct measurement of core temperature, or a direct estimate of core temperature that has been shown in research studies to be accurate to within 0.5°C of direct measurement. These sites are: pulmonary artery catheter, distal oesophagus, urinary bladder, zero heat-flux (deep forehead), sublingual, axilla, rectum.

2. Preoperative phase:

The preoperative phase is defined as the hour before induction of anaesthesia, during which the patient is prepared for surgery.

- Each patient should be assessed for their risk of inadvertent perioperative hypothermia and potential adverse consequences before transfer to the theatre suite.
- Patients should be managed as higher risk if any 2 of the following apply:
 - a) American Society of Anesthesiologists (ASA) grade II to V (the higher the grade, the greater the risk)

- b) Preoperative temperature below 36.0°C (and preoperative warming is not possible because of clinical urgency)
- c) Undergoing combined general and regional anaesthesia
- d) Undergoing major or intermediate surgery
- e) At risk of cardiovascular complications
- The patient's temperature should be measured and documented in the hour before the surgery.
- If the patient's temperature is below 36.0°C, start active warming preoperatively unless there is a need to expedite surgery because of clinical urgency.
- If the patient's temperature is 36.0°C or above, start active warming at least 30 minutes before induction of anaesthesia, unless this will delay emergency surgery.
- Forced air warming seems to have beneficial effect in terms of a lower rate of surgical site infection and complications, at least in those undergoing abdominal surgery, compared to not applying any active warming systems.
- Maintain active warming throughout the intraoperative phase.
- On transfer to the theatre suite:
 - active warming should be continued (or re-started as soon as possible)
 - the patient should be encouraged to walk to theatre where appropriate.

3. Intraoperative phase

The intraoperative phase is defined as total anaesthesia time, from the first anaesthetic intervention through to patient transfer to the recovery area of the theatre suite.

- The patient's temperature should be measured and documented before induction of anaesthesia and then every 30 minutes until the end of surgery.
- Induction of anaesthesia should not begin unless the patient's temperature is 36.0°C or above (unless there is a need to expedite surgery because of clinical urgency, for example bleeding or critical limb ischaemia).
- In the theatre suite the ambient temperature should be at least 21°C while the patient is exposed. The ambient temperature may be reduced once active warming is established to allow better working conditions using equipment to cool the surgical team.
- The patient should be adequately covered throughout the intraoperative phase to conserve heat, and exposed only during surgical preparation.
- Intravenous fluids (500 ml or more) and blood products should be warmed to 37°C using a fluid warming device.
- Warm patients intraoperatively from induction of anaesthesia, using a forced-air warming device, if they are:
 - a) having anaesthesia for more than 30 minutes or
 - b) having anaesthesia for less than 30 minutes and are at higher risk of inadvertent perioperative hypothermia.

Consider a resistive heating mattress or resistive heating blanket if a forced-air warming device is unsuitable.

- The temperature setting on forced-air warming devices should be set at maximum and then adjusted to maintain a patient temperature of at least 36.5°C.
- All irrigation fluids used intraoperatively should be warmed in a thermostatically controlled cabinet to a temperature of 38°C to 40°C.

4. Postoperative phase

The postoperative phase is defined as the 24 hours after the patient has entered the recovery area of the theatre suite.

- The patient's temperature should be measured and documented on admission to the recovery room and then every 15 minutes.
- If the patient's temperature is below 36.0°C, they should be actively warmed using forced-air warming until they are discharged from the recovery room or until they are comfortably warm.
- Patients should be kept comfortably warm when back on the ward.
- If the patient's temperature falls below 36.0°C while on the ward: they should be warmed using forced-air warming until they are comfortably warm. Their temperature should be measured and documented at least every 30 minutes during warming [4, 5].

Hyperglycemia Prevention

Blood glucose levels rise during and after surgery due to surgical stress. Surgery causes a stress response that results in a release of catabolic hormones and the inhibition of insulin. Moreover, surgical stress influences pancreatic beta-cell function, which results in lower plasma insulin levels. Taken together, this relative hypoinsulinaemia, insulin resistance and excessive catabolism from the action of counter-regulatory hormones make surgical patients at high risk for hyperglycaemia, even non-diabetic patients. [6]

Several observational studies showed that hyperglycaemia is associated with an increased risk of SSI and therefore an increased risk of morbidity, mortality and higher health care costs in both diabetic and non-diabetic patients and in different types of surgery .

A recent systematic review and cohort meta-analysis including 16 studies [7] concluded that use of an evidence- based, surgical care bundle for patients undergoing colorectal surgery significantly reduced the risk of SSI. Although none of the studies in this analysis used the identical SSI care bundles, all included elements from a core group of interventions, including appropriate antibiotic prophylaxis, normothermia, appropriate hair removal, and glycemic control for hyperglycemic patients.

Hyperglycemia is a known risk factor for infection because it impedes the normal physiologic responses to infection. In vivo studies show that hyperglycemia is associated with accelerated nonenzymatic glycosylation of proteins or the nonenzymatic addition of sugar molecules to the exposed lysine residues on extracellular proteins. Short-term glycosylation of immunoglobulins inactivates them. Furthermore, hyperglycemia impairs leukocyte function, including abnormalities in granulocyte adherence, impaired phagocytosis, delayed

chemotaxis, and depressed bactericidal activity. The degree of hyperglycemia that has been shown to impair phagocytic function, both in vivo and in vitro, is approximately 200 mg/dL. More important, the degree of phagocytic impairment can be reversed with control of glucose level. [8]

Conflicting results have been reported regarding the different treatment options to control hyperglycaemia in diabetic and non-diabetic patients, the optimal target levels of blood glucose and the ideal timing for glucose control (intra- and/or postoperative). The general consensus remains that glucose levels greater than 200 mg/dL is detrimental, but the lower limit and the tightness of control is debatable. Moreover, some studies targeting relatively low perioperative glucose levels have highlighted the risk of adverse effects associated with intensive protocols as they may cause hypoglycaemia. [9]

Overall low-quality evidence shows that a protocol with more strict blood glucose target levels has a significant benefit in reducing SSI rates when compared to a conventional protocol. There was evidence that the effect was smaller in studies that used intensive blood glucose controls intraoperatively only compared to studies that used an intensive protocol postoperatively or both intra- and postoperatively.

Meta-regression analysis showed that the benefit of an intensive protocol over a conventional protocol was consistent in both patients with and those without diabetes, and whether commenced during or after surgery. Among the intensive protocols, the effect was similar in studies with a target blood glucose level of ≤ 110 mg/dL and an upper limit target level of 110-150 mg/dL. [10]

Five studies reported significantly more hypoglycaemic measurements in the intensive group compared with the control group. Although these events were asymptomatic, with none of the studies reporting clinical consequences, it remains unknown to what extent these hypoglycaemic episodes harm patients in the long term and whether this potential harm outweighs the reduced risk of SSI. [10]

Targeting stricter and lower blood glucose levels with an intensive protocol of perioperative glucose control reduces SSI without increasing the risk of death or stroke. Although the optimal target level cannot be derived from published data, the summary data of present systematic review and meta-analysis indicate that target glucose levels of less than 150 mg/dl in the perioperative period can be achieved safely with minimal risk of asymptomatic hypoglycaemic events and with no significant increase in serious adverse events. [10]

Due to the risk of hypoglycaemia, targeting lower levels should be avoided. While most recommendations focus on the diabetic patient only, those issued by SHEA/IDSA and the American College of Physicians apply to all surgical patients. They recommend either target levels between 140-200 mg/dL or upper limits of 180 mg/dL or 198 mg/dL. [6]

Thus, the Global Guidelines for the prevention of surgical site infection endorsed by WHO, unanimously agreed that the recommendation to use protocols for intensive perioperative blood glucose control should apply to both diabetics and non-diabetics. However, the available evidence did not allow the definition of an optimal target level of blood glucose. [6]

Normovolemia

Wound infections are serious complications of surgery. Oxidative killing by neutrophils is the most important defense against pathogens causing surgical infections. Because oxygen is the substrate for oxidative killing, the rate of bacterial killing depends on sufficient tissue oxygenation. Wound healing and resistance to infection are dependent on tissue oxygen tension. Sufficient tissue oxygenation is essential for collagen synthesis and wound repair and is improved by adequate arterial oxygenation. [11] Ideally, perioperative fluid therapy prevents tissue hypoxia by maximizing the cardiac output and thus improving arterial oxygenation.

Fluid overload leads to a decrease in muscular oxygen tension. Due to surgical trauma, a systemic inflammatory response arises, which leads to a fluid shift to the extravascular space. Following a large fluid shift, generalized oedema may occur, which decreases tissue oxygenation and impedes tissue healing. By contrast, hypovolemia leads to arterial and tissue hypoxia due to a decrease in cardiac output. The optimal fluid (colloid or crystalloid) or strategy of fluid management (goal-directed, liberal or restricted) remains a subject of controversy. [1]

Perioperative goal-directed therapy (GDT) aims to match the increased oxygen demand incurred during major surgery, by flow-based haemodynamic monitoring and therapeutic interventions to achieve a predetermined haemodynamic endpoint. [12] Several metaanalyses of RCTs have shown that goal-directed fluid therapy (GDT) reduces postoperative morbidity and length of hospital stay, especially in high-risk patients undergoing major surgery.

Few organizations have issued recommendations regarding the maintenance of normovolemia. The UK-based NICE recommends maintaining adequate perfusion during surgery. Based on an evidence update in 2013, it is stated that haemodynamic GDT appears to reduce SSI rates. [6]

Overall low quality evidence shows that intraoperative GDT has significant benefit in reducing the SSI rate compared to standard fluid management. This effect is shown also for GDT in the postoperative period. Considering the low quality evidence above-mentioned, the WHO in the second edition of the Global Guidelines for the prevention of surgical site infection agreed to suggest the use of GDT intraoperatively and decided that the strength of this recommendation should be conditional. [6] The guidelines developers group highlighted that a widely-accepted definition for normovolemia is needed. Future studies including large well-designed RCTs with clear definitions should aim at identifying the most accurate and least invasive method of measuring normovolemia and assess its influence with regard to tissue oxygenation and normothermia.

Peri-operative goal-directed therapy, using fluids and/or inotropes, typically involves the use of haemodynamic targets to optimize oxygen delivery. A systematic literature search identified three haemodynamic management goals: stroke volume optimization by fluid therapy; maintenance of a target mean arterial pressure by vasopressor therapy; maintenance of a target cardiac index ≥ 2.5 l/min per m² by inotropic therapy. [13] The use of an algorithm is helpful, while considering that local resources and expertise may vary and limit possibilities for the optimal strategy. Indeed, the variety of effective algorithms on a multitude of outcomes indicates that having an algorithm for a specific goal is the most important factor, more than any particular algorithm associated with the effect of GDT.

CONCLUSION

During surgery patients are kept in a stable condition by the operating team. All tissues heal most effectively in optimal conditions of oxygenation, perfusion and body temperature.

Intraoperative high FiO₂ may be regarded as a supplemental strategy to further decrease the risk of surgical site infection in patients receiving prophylactic antibiotics without increasing the risk of postoperative atelectasis.

Inadvertent perioperative hypothermia is a common but preventable complication of perioperative procedures that is associated with an increased risk of surgical site infection and other postoperative complications. Surgical patients are at risk of developing hypothermia before, during or after surgery. Maintaining normothermia throughout this period (except if cooling is required for medical reasons) will therefore reduce the risk of infection at the surgical site and ensure that patients feel comfortably warm at all times.

Hyperglycemia is a known risk factor for infection. Overall low-quality evidence shows that a protocol of control for blood glucose levels has a significant benefit in reducing SSI rates. The effect was similar in studies with a more intensive target blood glucose level and an upper limit target. Available evidence did not allow the definition of an optimal target level of blood glucose. Due to the risk of hypoglycaemia, targeting lower levels should be avoided.

At present, there is no universal definition of normovolemia or a standardized method for its assessment. Low quality evidence shows that intraoperative GDT has significant benefit in reducing the SSI rate. Considering that both fluid overload and hypovolemia are likely to affect other clinical outcomes, actual recommendations suggest the use of GDT intraoperatively, but the strength of this recommendation should be conditional.

ABSTRACT

Surgical site infections (SSI) are the most frequent complications in surgery procedures. Despite the use of standard surgical techniques (antiseptic skin preparation, sterile draping, and antibiotics) that could prevent perioperative wound infections, wound infection following clean-contaminated procedures occurs in more than 10%. SSI contribute substantially to postoperative morbidity and mortality and have been shown to significantly increase the mean length of hospital stays and treatment costs. Thus, devices to reduce SSI incidence are of great medical and economic importance. Adhesive draps and plastic wound protectors were originally designed to be a simple, easy-to-use, and cost-effective device that reduces the contact between bacteria and incisions,

and provides a relatively disease-free environment for the operator, which could reduce the SSI substantially.

Keywords: surgical site infections, plastic wound protectors, wound infection

INTRODUCTION

Surgical site infection (SSI) is one of the most common hospital acquired infections in the field of surgery. SSI leads to increased overall health care cost and is associated with a prolonged hospital stay, more complex wound care needs, more frequent visits to outpatient clinics, and higher rates of hospital readmission and morbidities [1]. Thus, SSI rates have been used to evaluate outcome measures of surgical quality worldwide. Risk factors affecting

* Corresponding Author's Email: cesdenlinares@gmail.com.

† Patricia Sanchez-Salcedo, RN.

the SSI rate can be categorized into 2 main groups: patient related and procedure related [2]. Patient-related factors include generally nonmodifiable factors such as patient age, body mass index, malnutrition, comorbidities (such as uncontrolled diabetes mellitus or anemia), and American Society of Anesthesiologists (ASA) score. Meanwhile, procedure-related factors can be controlled to a degree and therefore may be modified in an effort to reduce the risk of SSI; these include the method of skin preparation, meticulous dissection and reduced operating time, use of minimally invasive surgery compared with conventional open surgery, and use of prophylactic antibiotics. Physical wound protection can reduce the rate of SSI in patients undergoing abdominal surgery. Most abdominal surgeries are performed with a clean-contaminated or contaminated-incisional wound because these often require manipulation or resection of the bowel or biliary tract. In particular, emergency abdominal surgeries are more likely to consist of contaminated and dirty wounds. Therefore, in these cases, it is especially important to physically protect the incisional wound from sources of infection such as bowel content spillage to reduce the SSI rate. Adhesive drapes, antimicrobial skin sealants and impervious plastic wound protectors (IPWP)—so-called wound edge protectors, circular wound edge protectors or plastic ring wound protectors—have been used to protect the incisional wound and reduce SSI rates [3]. However, the effectiveness of these wound protectors on reducing the SSI rate remains unclear. For example, despite the expected clinical benefit of IPWP to reduce the rate of SSIs and the favorable results reported by several studies [4], some prospective series and randomized clinical trials (RCT) have reported disappointing results of the effect of IPWPs on reducing SSI rates in patients undergoing abdominal surgery [5]. In this chapter, we will analyze the effectiveness of each of the devices used in the protection of the skin and the surgical wound in patients undergoing abdominal surgery and the updated recommendations on their use.

WOUND PROTECTORS

The use of adhesive membrane barriers over the skin of the surgical site emerged 50 years ago as a possible solution to minimise endogenous cross-contamination during surgery [6]. The initial idea relied on the principle of reducing exposure of the surgical site to bacteria inherent in the surrounding skin or to airborne bacteria in the operating room. Major applicability was expected in clean surgeries, where the skin is considered the main source of bacteria. Unfortunately, however, no evidence in support of plastic adhesive drapes was found in a recently updated systematic review RCT including five studies and 3082 participants(2). In fact, a 23% increase in the risk of SSI was found in the group that received adhesive drapes. In the 1960s, other devices were described and then developed based on the concept of combining a non-traumatic surgical wound retractor with a protective membrane covering of the incisional margin in abdominal surgeries. Such protective covers or ‘wound protectors’ were hypothesised to be an improvement over adhesive membrane barriers as they were believed to reduce intraoperative contamination while concomitantly preserving the temperature and humidity of the surgical wound. In support of this hypothesis, early studies demonstrated reduced exposure of the surgical wound to enteric bacteria at the end of gastrointestinal operations [7, 8]. These results were further supported by several RCT, which demonstrated that wound protectors were efficacious in reducing the incidence of incisional

SSI as compared to usual care in patients undergoing gastrointestinal surgeries [4, 9, 10]. There are different impervious circular wound edge protectors (CWEP), but they all fall into two main categories: a.) devices with a single semirigid plastic ring placed into the abdominal cavity after laparotomy with an impervious drape attached, which comes out of the abdomen to protect the incisional edges (single-ring device) and b.) devices with two semi-rigid plastic rings connected by an impervious drape (Figure 1).

Figure 1. Circular wound edge protectors (CWEP). A single-ring device. B double-ring device [11].

Table 1. Recommendations on the use of WP devices according to available guidelines [14]

Guidelines (year issued)	Recommendations on the use of WP devices
SHEA/IDSA practice recommendation (2014)	Use impervious plastic WPs for gastrointestinal and biliary tract surgery.
NICE (2013 update)	Wound edge protection devices may reduce the SSI rate after open abdominal surgery, but the current lack of high-quality studies implies that more research is needed.

These new surgical devices comprise a non-adhesive plastic sheath attached to a single or double rubber ring that firmly secures the sheath to the wound edges. The device is intended to facilitate the retraction of the incision during surgery without the need for additional mechanical retractors and cloths. Theoretically, commercially-available CWEP are intended to reduce wound edge contamination to a minimum during abdominal surgical procedures, including contamination from outside (clean surgery) and inside the peritoneal cavity (clean-contaminated, contaminated and dirty surgery). Although these surgical devices are already on the market, their real usefulness and cost-effectiveness warrants additional evidence-based analysis. Few organizations have issued recommendations regarding the use of CWEP devices. The UK-based NICE states that wound edge protection devices may reduce SSI rates after open abdominal surgery, but no recommendation is given due to the lack of further high-quality evidence [12]. However, SHEA/IDSA guidelines recommend the use of impervious plastic CWEP for gastrointestinal and biliary tract surgery [13].

While CWEP effectively protect wound edges from bacterial invasion their clinical effectiveness has been disputed and their widespread use has been hampered by conflicting trial results with some authors reporting beneficial effects [10] while others found no benefit [15].

Two previous smaller reviews based on limited patient numbers and low-quality evidence reported a beneficial effect of CWEP, but called for adequately powered, high-quality trials [16] which have been conducted since then. A recently meta-analysis of RCT, evaluated whether diverse types of wound protectors may reduce the risk of SSI among patients undergoing gastrointestinal or biliary surgery [17]. Among six trials, which enrolled 1008 patients, it was found that the pooled estimated risk of SSI among patients fitted with wound protectors during surgery was 0.55 (95% CI 0.31 to 0.98) times the pooled estimated risk of SSI in control groups. Moreover, among patients treated with dual-ring versus single-ring wound protectors, the pooled estimated risk of SSI was 0.31 (95% CI 0.14 to 0.67) times the pooled estimated risk in the control groups. As blinding status of outcome assessors was identified as a significant source of between study heterogeneity, the design of the wound protector as well as the method of outcome classification may be important considerations for the design of future wound protector trials.

According to the actual evidence, it is recommended the use of CWEP devices in clean-contaminated, contaminated and dirty abdominal surgical procedures for the purpose of reducing the rate of SSI.

ADHESIVE DRAPES AND GOWNS

Drapes and gowns are available for single-use or multiple-use, with varying compositions. Adhesive plastic incise drapes are used on a patient's skin after surgical site preparation, with or without antimicrobial impregnation, and the surgeon performs the incision of the drape and the skin simultaneously. In available guidelines, there are conflicting recommendations on the use of plastic adhesive drapes, mainly discouraging their use. There are no recommendations on the use of single-use or reusable drapes and gowns for the purpose of SSI prevention. We did a systematic review to investigate the use of sterile disposable or reusable drapes and surgical gowns, and separately the use of plastic adhesive incises drapes, for the purpose of SSI prevention. Results from non-randomised studies have produced conflicting results about the efficacy of this approach, but no systematic review has been conducted to date to guide clinical practice. A recent meta-analysis [2] of the impact of adhesive drapes on SSI included 5 studies with a total 3082 patients comparing adhesive drapes versus no drape, and 2 with a total 1113 patients comparing iodine-impregnated adhesive drapes versus no drape. SSI rates were higher in the adhesive drape groups; iodine impregnation was not associated with any significant difference in SSI. The WHO also performed a meta-analysis assessing adhesive drapes with and without antiseptic impregnation [14] and found no benefit in terms of SSI between using or not using adhesive drapes. Some allergic reactions occurred with impregnated drapes.

Considering the evidence, including potential issues of availability and costs in low-resource settings and the ecological effect, the expert panel suggested that either sterile disposable non-woven or sterile reusable woven drapes and gowns can be used. However,

adhesive incise drapes (with or without antimicrobial properties) should not be used for the purpose of preventing SSI.

ANTIMICROBIAL SKIN SEALANTS

Antimicrobial skin sealants, usually composed of cyanoacrylate, are sterile liquids applied to the skin after skin preparation, ahead of incision; on drying, they form a film that is meant to prevent migration towards the surgical site for several days. The WHO experts performed a meta-analysis of the contribution of antimicrobial skin sealants to prevention of SSI, based on 8 randomized trials and 1 observational study, with a total 1974 patients [14], and found no significant impact compared to standard skin preparation. Cyanoacrylate is a generic term referring to a class of compounds that readily polymerize to create sealants. The first cyanoacrylates were discovered in 1942 when searching for a compound that would form a solid adhesive for weapon development. Noted as a wondrous compound that stuck to everything it came into contact with, it quickly fell out of favor. With time, however, uses for these compounds were reexplored. Perhaps the most well-known, household cyanoacrylate, ethyl-2-cyanoacrylate, is more commonly known as SuperGlue. In 1998, the Food and Drug Administration (FDA) approved another cyanoacrylate, 2-octyl-cyanoacrylate, for use as a surgical incision sealant.

More commonly known by trade names such as Dermabond (Ethicon, Somerville, NJ), this compound readily polymerizes when exposed to skin, blood, or moisture creating a barrier to the migration of bacteria into surgical incisions. Additionally, cytotoxic compounds released by this polymerization reaction exhibit bactericidal properties [18].

A number of studies have tried to ascertain if cyanoacrylates can effectively reduce the rate of SSI. Again, results have been mixed and study subject numbers small making it difficult to make a recommendation supporting the widespread use of this compound for the purpose of reducing SSI, particularly in light of its expense. In 2010, Chambers et al. performed a best evidence review evaluating the use of cyanoacrylate glue on sternal surgical incision infections. In this review, a substantial benefit reducing both superficial and deep surgical incision infections in cardiac surgery was observed when cyanoacrylate was applied post-operatively (4.9% versus 2.1%) or even preoperatively (10.8% versus 2.7% or 7.8% versus 1.1% depending on the study) [19]. Enthusiasm for applying these antimicrobial sealants immediately prior to incision has been particularly observed in the cardiothoracic literature. In 2011, Iyer et al. published a study evaluating patients undergoing cardiac bypass in which saphenous vein harvesting was performed bilaterally. In each patient, one leg was pre-treated with sealant whereas the contralateral leg was not pre-treated. Treated legs developed a 2% incidence of infection, whereas untreated legs became infected in 25% of patients. The study was terminated after 47 patients were enrolled [20]. A larger, randomized trial by von Eckardstein et al. comparing patients who underwent cardiac surgery, allocated 146 patients to pretreatment with cyanoacrylate sealant to sternal and graft harvest sites and 147 patients to no treatment. In this study, there was a 35% relative risk reduction in the rate of SSI in pretreated patients. Furthermore, in subgroup analysis, this study showed an 83% relative risk reduction in obese patients who received pre-treatment [21].

In 2010, Lipp et al. performed a systematic review submitted to the Cochrane Database including all randomized trials evaluating the use of cyanoacrylate sealants as a pretreatment of skin incisions. Sufficient evidence supporting the use of such sealants was not found and studies noted to be lacking in rigor and quality [22]. In 2014, Vierhout et al. randomized 47 patients undergoing lower extremity revascularization surgery to closure with cyanoacrylate. Although there was a trend to less SSI (4% vs 9%), this study failed to reach statistical significance [23].

Therefore—also to avoid unnecessary costs—antimicrobial sealants should not be used after surgical site skin preparation for the purpose of reducing SSI.

IMPREGNATED DRESSINGS

The 1999 Guideline for Prevention of Surgical Site Infection is clear in its recommendations for management of post-operative surgical incision dressings stating that surgical incisions should be protected with a sterile occlusive dressing for 24 to 48 h post-operatively [24]. Furthermore, when a dressing must be changed, sterile technique should be employed. Beyond simple sterile dressings, there has been question raised as to the benefit of enhancing dressings with antibacterial agents. In particular, a number of studies have attempted to show improved surgical incision healing and decreased SSI in surgical incisions treated with silver impregnated surgical incision dressings. It has long been believed that silver containing compounds have antibacterial properties. In 2011, the Cochrane Database released a review of sixteen randomized trials employing silver impregnated dressings. Unfortunately, it was noted that these trials were too small and of poor quality. It was concluded that there is no evidence that one type of dressing is better than another. In addition, one study even showed slowed surgical incision healing in patients treated with impregnated dressings. In 2012, Biffi et al. again evaluated the use of silver impregnated dressings in patients undergoing surgery for colorectal cancer. Fifty-eight patients' surgical incisions were covered with silver-impregnated dressings and 54 patients' surgical incisions were covered with standard dry sterile dressings. After a follow-up of 30 days, a trend to fewer surgical site infections were noted in the silver dressing group (15.5% vs 20.4%), but this was not statistically significant [25].

Chapter 279

WOUND IRRIGATION

Gilberto González Ramírez*

Centro Medico Puerta de Hierro, Guadalajara Jalisco, México

ABSTRACT

There are different challenges in the course of a surgery treatment. These go from the type of surgical procedure until the adequate close of the incision. In this scenario, the wound needs an environment that gives the best or almost the best conditions for normal healing. In such conditions, to avoid surgical site infection (SSI) at the time of the surgery or later and to keep clean the wound is one of the main factors to achieve a good environment with the sequence of hormonal activation and inflammatory response, stimulating the regeneration of the tissue with a properly closure. In this chapter, we will talk about the wound irrigation, the different type of solutions to do it, which one is more effective and why in our opinion, and which is the actual consensus about this practice. There are several opinions and different experiences around the world, sometimes more supported by evidence and other not so much.

Keywords: wound irrigation, wound management, surgical site infection, incision, solutions, healing, clousure

INTRODUCTION

Despite extensive scrutiny, multiple collaborative efforts, and significant advances in infection prevention practices, approximately 500,000 surgical site infections (SSIs), with an associated cost estimated at \$10 billion, occur annually in the United States alone [1, 2].

At the 2013 annual Association for Professionals in Infection Control and Epidemiology conference, a focus group of key thought leaders in infection prevention and epidemiology,

* Corresponding Author's Email: gilpchmd@yahoo.com.mx.

including epidemiologists, surgeons, and infection prevention directors for major health care systems, convened to address the implications of different surgical irrigation practices. The group agreed that, in an era where health care-associated infections rank as the fifth leading cause of death [3] and carry an attributable per patient cost ranging from \$80,000 to \$110,000 [4, 5], closer investigation of surgical irrigation practices, as an integral part of the infection prevention process, is warranted [1].

A complete wound history along with anatomic and specific medical considerations for each patient provides the basis of decision making for wound management. It is essential to apply an evidence-based approach and consider each wound individually in order to create the optimal conditions for wound healing [6].

Without proper cleansing and wound care, these acute wounds can lead to complications, such as poor healing and infection. Optimizing wound healing through proper acute wound management involves removal of harmful debris/necrotic tissue, exploration for underlying injuries, control of bacterial burden and appropriate closure [6].

BACKGROUND

Surgical Site Infection

Postoperative surgical site infection (SSI) represents as one of the most frequent complications following abdominal surgery. In the USA, an estimated 300,000 to 500,000 cases of SSI occur annually [8, 24]. Similar figures are reported from Germany [7, 9], the UK [10], and France [11]. The incidence of SSI varies substantially, depending on the type and site of surgery [8]. According to recent high-level randomized controlled trials (RCTs) with standardized SSI definitions, rates range from around 15 % (BaFo trial [12]; PROUD trial [13] up to 25 % (ROSSINI trial) [14] following laparotomy for visceral surgery. SSIs contribute substantially to postoperative morbidity and mortality and have been shown to significantly increase the mean length of hospital stay and treatment costs [11, 15, 24]. Therefore, measures to prevent SSI are urgently needed [16].

Surgical site infections are recognized as a common surgical complication, occurring in about 3% of all surgical procedures and in up to 20% of patients undergoing emergency intra-abdominal procedures [17, 18].

Surgical site infections (SSIs) are an adverse outcome of surgery accounting for the majority of healthcare-associated infections around the world [20, 21]. In developing countries, more than one in ten of all surgical procedures is complicated by an SSI [22]. Although the overall risk of SSIs is much lower in developed countries, they remain a serious threat to patient safety [20, 21]. Such infections increase morbidity and mortality rates and prolong hospital stays [19, 20, 23, 24].

Many factors have been associated with the risk of SSI, and consequently, a range of preventive measures has been proposed. One of these is prophylactic intra-operative wound irrigation (pIOWI), a seemingly simple intervention defined by the flow of a solution across the surface of an open wound to achieve tissue hydration. It removes and dilutes body fluids, bacteria, and cellular debris and additionally may have a bactericidal effect when additives, such as antibiotics or antiseptic agents are used (see Table 1 for an overview of the definitions

used). As many as 97% of surgeons commonly practice IOWI [25, 26]. Nonetheless, it is not part of general practice in every country or hospital. Moreover, methods differ depending on the patient population, surface of application, technique, and solutions used. Similar variations in methods and results can be observed in studies investigating the effect of IOWI [18, 27, 28].

Among the available guidelines on SSI prevention, few have addressed the topic of IOWI and give contradictory recommendations. The guidelines from the United Kingdom National Institute for Health and Care Excellence (NICE), issued in 2008 and updated in 2013, advised against IOWI and intra-peritoneal lavage [29]. In contrast, the 2014 guidelines of the Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA) recommend using antiseptic incision lavage [28]. Many of the solutions commonly used for irrigation are not licensed for open incisions by the U.S. Food and Drug Administration [18, 28, 30].

Infection may occur within the surgical site at any depth, starting from the skin itself and extending to the deepest cavity that remains after resection of an organ. Superficial SSI involves tissues down to the fascia (Figure 1), whereas deep SSI extends beneath the fascia but not intracavitary. Organ/space infections are subfascial or intracavitary, but if related directly to an operation, are considered to be SSIs [18].

Table 1. Systematic Review and Meta-Analysis of Randomized Controlled Trials Evaluating Prophylactic Intra-Operative Wound Irrigation for the Prevention of Surgical Site Infections Stijn W. de Jonge,^{1,*} SURGICAL INFECTIONS Volume 18, Number 4, 2017 a Mary Ann Liebert, Inc. DOI: 10.1089/sur.2016.272 [19]

Prophylactic intra-operative wound irrigation (pIOWI)	The flow of a solution across the surface of an open wound to achieve wound hydration. It physically removes and dilutes body fluids, bacteria, and cellular debris and has a bactericidal effect when additives such as antibiotics or antiseptic agents are used
Intra-operative wound irrigation as therapeutic intervention	CDC wound class IV was considered a pre-existent infection; irrigation field was considered to be therapeutic, not prophylactic
Intra-operative wound irrigation as prophylactic intervention	CDC wound class I–III was considered potentially contaminated; irrigation was considered to be prophylactic Irrigation of the newly made incision was always considered prophylactic, regardless of the wound classification, as the incision did not exist prior to the procedure and established infection was impossible.
Syringe pressure irrigation	Solution delivered with a syringe with an intravenous catheter applying force by hand.
Pulse pressure irrigation	Irrigation with a mechanical device that delivers pulsatile saline irrigation.
US Centers for Disease Control and Prevention (CDC) surgical wound classification	Class I/Clean: An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. In addition, clean sites are closed primarily and, if necessary, drained with closed drainage. Operative incisions that follow non-penetrating (blunt) trauma should be included in this category if they meet the criteria. Class II/Clean–Contaminated: An operative wound in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered. Class III/Contaminated: Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract, and incisions in which acute, nonpurulent inflammation is encountered, are included in this category. Class IV/Dirty–Infected: Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation.

Cellulitis is infection-related erythema of skin (although other tissues may be affected) without drainage or fluctuance. Abscess refers to localized collections of purulent material within tissue. Necrotizing soft tissue infections (NSTIs) invade tissue widely and rapidly, causing widespread tissue necrosis. When fascia is involved, the infection is referred to correctly as necrotizing fasciitis [18].

Bacteria's Biofilm

The importance of biofilm formation as an element of wound infection has recently been stressed [31]. When bacteria proliferate in wounds, they form microcolonies, which attach to the wound bed and secrete a glycocalyx, or any kind of extracellular matrix, and take up an inter- dependent surface-attached existence. These microbial communities, called 'biofilms,' protect the organisms against antibiotics, antiseptics and host immune defences [32]. Almost all bacterial species form biofilm in vivo [33], thus representing a therapeutic challenge in many, if not most, bacterial diseases. Biofilm formation has also been linked to the emergence of a variety of opportunistic pathogens, such as *Staphylococcus epidermidis* and *Pseudomonas aeruginosa*, which contribute to persistent infections by changing environmental parameters [34, 84].

Definitions

Primary closure, also known as healing by first intention, represents closure of a wound at the time of initial presentation. Wound edges are approximated with suture, adhesives, staples, or strips after appropriate wound management techniques are applied.

Delayed primary closure represents a delay in wound closure for approximately 3–5 days. This is ideal for delayed presentations or for wound infection concerns. If there are no signs of infection and the wound margins appear healthy, removal of devitalized tissue and subsequent primary closure is appropriate.

Healing by secondary intention represents those wounds that are allowed to heal through contraction—a natural, unaided physiologic property. While appropriate wound management practices are involved, no attempt is made to aid wound closure [6].

Clean surgical procedures are those where the operation has affected only integumentary and musculoskeletal soft tissues. Clean- contaminated procedures are those where a hollow viscus (e.g., alimentary, biliary, genitourinary, respiratory tract) has been opened under controlled circumstances (e.g., elective colon surgery). Contaminated procedures are those where bacteria has been introduced extensively into a normally sterile body cavity, but for a period of time too brief to allow infection to become established during surgery (e.g., penetrating abdominal trauma, enterotomy during adhesiolysis for mechanical bowel obstruction). Dirty procedures are those where the surgery is performed to control established infection (e.g., colon resection for complicated diverticulitis) [18].

Normal acute wounds usually progress through an orderly sequential trajectory of hemostasis, proliferation, maturation, and remodeling [35]. After initial injury to the dermal tissue, hemostasis is established by platelet aggregation, fibrin clot formation, and the subsequent coagulation pathways. Local migration of neutrophils and macrophages initiates

an acute inflammatory response to help prevent microbial overgrowth as well as initiate wound healing. During the proliferative phase, deficiencies in soft tissue are replaced with healthy new granulation tissue and matrix material. As healing progresses, the majority of type III collagen formed by fibroblasts is converted to type I collagen to enhance soft tissue strength and integrity [6, 36].

Figure 1. Surgical site infections. (Adapted from Mangram AJ, Horan TC, Pearson ML, et al. The Hospital Infection Control Practices Advisory Committee. Guideline for the prevention of surgical site infection, 1999. *Infect Control Hosp Epidemiol* 1999; 20:247-80).

To ensure the normal physiology of healing, wounds must have sufficient blood supply. Inflammation, infection, or residual debris may delay or prevent adequate healing. As healing occurs, wound tensile strength will approach 20% at 3 weeks and 60% by 4 months [6, 35].

The primary goals for wound care are to attain a functional closure, decrease potential risk for infection, and minimize scar formation [6, 37].

Proper wound preparation improves healing and outcomes. While evidence-based recommendations for wound care exist, many practitioners continue to treat wounds based on personal preference—some employing unnecessary or possibly detrimental techniques [6, 38].

Pressure Irrigation

Wound irrigation is arguably the most important step for optimizing wound healing as long as there is sufficient pressure and volume. Irrigation pressure recommendations that are often cited in the literature come mostly from studies in chronic wounds (such as pressure ulcers). Many studies either failed to describe how pressure was measured or identify the actual realized pressure on the tissues. Within the realm of acute wound management, the term ‘high pressure’ irrigation is frequently used to describe the best practice for wound irrigation. However, it is important to understand that this term reflects a wide range of pressures and a paucity of well-supported literature as to the deliverable irrigant pressure [6].

Classically, equipment used for irrigation has included bulb syringes, syringes with an attached needle or catheter, intravenous or irrigation fluid in plastic containers with a pour cap or nozzle, and pressure canisters. Puncturing containers of irrigation fluid and manually

squeezing are inadequate for pressure irrigation [39]. Studies have shown that when using a syringe with an attached 19-gauge needle, pressures range from 11 to 31 psi—however, only 8 psi may reach the wound [39, 40]. Current medical devices have been designed to provide a more consistent and measurable application of wound irrigation pressure. Clinicians currently believe that these advances may provide a better approach to wound cleansing [6, 41].

There is some evidence that very high pressure irrigation may actually increase infection rates due to further tissue damage. This is particularly evident in highly vascularized wounds, such as the face and scalp [6, 42].

A study by Chisholm found no difference in infection rates of lacerations that required closures when irrigation was done using a pressure canister compared to a syringe/needle irrigation (5.0% vs. 3.6%; $P = 0.05$) [43]. Longmire found that high pressures of 13 psi, generated by using a needle and syringe, were effective in reducing inflammation and infection when compared to irrigation using a bulb syringe associated with lower pressures [40]. Pressures of 8–12 psi in the wound are believed to overcome the adhesive forces of the introduced bacterium [40, 43]. However, both of these studies were limited by the inability to measure consistent pressures across the tissue beds being irrigated [6].

Irrigation Volume

Irrigation volumes of 50 to 100 ml per cm of laceration length have been reported [44, 43]. The volume of irrigation should be adjusted to the wound characteristics and degree of contamination. All wound surfaces should be irrigated and may require pulling open the wound edges and flaps for exposure [44]. Repeat irrigation has been recommended after any re-examination of the wound [6, 45].

Irrigation Solution

Decontamination, including brushing off any dry chemicals prior to copious irrigation, is an essential part of the initial wound management. It is important to consider toxicological exposure as it relates to wound irrigation. Antiseptic solutions, such as povidone-iodine, chlorhexidine, and hydrogen peroxide, are toxic to tissues and may impede acute wound healing [41]. The current literature supports no difference in ED wound infection rates when using potable tap water versus saline in adult and pediatric populations [46]. Further, studies comparing saline irrigation with diluted 1% povidone-iodine have shown no difference in infection rates [43, 47, 48]. A study of chemical burns ($N = 24$) recommended copious amounts of potable tap water or saline for irrigation and decontamination [6, 49].

There are 3 critical variables in the surgical irrigation process: delivery, volume, and solution additives. In the absence of formal guidelines, anecdotal evidence suggests that a wide variety of practices are used with regard to each of these three variables [1].

Delivery

Surgical irrigation delivery includes choosing delivery method, pressure (the American College of Surgeons [ACS] defines high pressure as 15 to 35 psi and low pressure as 1 to 15 psi [50], and continuous or pulsatile flow. Neither the ACS nor the Association of periOperative Registered Nurses (AORN) has published practice recommendations on surgical irrigation delivery [1].

A number of studies have been performed to evaluate optimal pressures for wound irrigation. The majority of these have shown high-pressure irrigation to be most effective in bacteria and foreign material removal; however, high-pressure irrigation has also been associated with impairment of the local immune response, tissue damage, and propagation of bacteria deeper into tissue or bone [51]. These negative effects suggest that high-pressure lavage should be limited to conditions where contamination is severe and the anticipated difficulty in bacterial removal outweighs the potential of propagation of bacteria [51]. Whereas no official guidelines exist for optimal pressures, recommendations have suggested utilizing pressures of 8 to 12 psi in traumatic wounds in an effort to overcome the adhesive forces of bacteria [1, 52].

Volume

Similar to the lack of data on delivery of surgical irrigation, there are no official recommendations on irrigant fluid volumes [51]. Additionally, there are no published human studies. Animal studies have indicated that increasing volume improves bacteria and foreign material removal to a point, but excessive volume also reduces the concentration of beneficial cytokines involved in the correct healing procedure. Thus, optimal volumes remain undefined [1, 51, 53].

Additives

Over the years, however, a variety of different additives, commonly grouped into the categories of antibiotics, surfactants, and antiseptics, have been combined with irrigation fluids in an attempt to optimize infection prevention. Unfortunately, there are few well-designed clinical trials looking at these practices and, hence, no established clinical guideline [1, 54].

Intraoperative Wound Irrigation (IOWI)

Intraoperative wound irrigation is the flow of a solution across the surface of an open wound to achieve wound hydration and it is widely practised to help prevent SSI [55, 56]. It is intended to act as a physical cleaner by removing cellular debris, surface bacteria and body fluids, to have a diluting effect on possible contamination, and to function as a local

antibacterial agent when an antiseptic or antibiotic agent is used. Up to 97% of surgeons state that they use intraoperative irrigation [55, 57].

However, practices vary depending on the patient population, the surface of application and solutions used. Similar variations in methodology and results can be observed in studies investigating the effect of wound irrigation [57, 58].

Results Forty-one RCTs reporting primary data of over 9000 patients were analyzed. Meta-analysis on the effect of IOWI with any solution compared to no irrigation revealed a significant benefit in the reduction of SSI rates (OR = 0.54, 95% confidence Interval (CI) [0.42; 0.69], $p < 0.0001$) [16].

Meta-analysis showed a significant benefit of IOWI with any solution in comparison to no irrigation [16].

Further, sub- group analysis showed that the estimated effect in reduction of postoperative SSI was significant only for IOWI with topical antibiotics or PVP-I but not for saline [16].

IOWI with Saline

Plain saline is a widely used irrigation solution, as it is isotonic and does not interfere with wound healing [59]. Furthermore, it is generally used to clean wounds from blood clots and necrotic tissue. However, evidence for IOWI with saline to prevent SSI is scarce. Only three RCTs comparing saline with no irrigation were identified [60, 61, 62], and meta-analysis showed no statistically significant effect on the rate of SSIs (Figure 4c, OR = 0.64, 95% CI [0.28; 1.46], $p = 0.29$) [16].

IOWI with PVP-I

Much debate has also surfaced over the use of PVP-I, and the use of this solution has been removed from many wound management regimes because of a putative negative effect on tissue regeneration. PVP-I demonstrates dose-dependent levels of tissue toxicity but is still better tolerated than preparations containing chlorhexidine or octenidine [63]. However, when studied in a clinical context, a recent evidence-based review of the effects of PVP-I solutions on wound healing failed to show a negative effect [64]. Consequently, the majority of high-quality trials analyzed in that review supported the use of PVP-I for IOWI. The NICE guidelines do not recommend the use of IOWI or intra-operative skin disinfection with PVP-I products [10, 16, 65]. Nevertheless, the recently published recommendations for SSI prophylaxis by the World Health Organization (WHO) recommend its use at a 10% concentration, diluted in plain saline [83].

IOWI with Topical Antibiotics

In clinical practice, IOWI with solutions containing antibiotics used to be widespread in the 1980s, especially in dirty-contaminated abdominal or trauma/orthopedic surgery [66].

Currently, guidelines do not support the use of antibiotic IOWI anymore, due to the lack of evidence for their benefit and the potential enhancement of microbial resistance [10, 16].

Especially in obese patients, who are predisposed to develop SSI, infusion of topical antibiotics to the wound allowed to achieve higher local concentrations in the poorly perfused subcutaneous adipose tissue than by intravenous application [67]. In line with this data, a significant reduction of SSIs in this subgroup analysis of 19 trials comparing IOWI with antibiotic solutions vs. no irrigation (Figure 4a; OR = 0.39, 95% CI [0.27; 0.55], $p < 0.0001$). However, different antibiotics, concentrations, and applications were used meaning that heterogeneity was high and no regime can currently be recommended unequivocally [16].

HOWEVER IN ONE META-ANALYSIS THE AUTHORS CONSIDERED...

Evidence of low quality shows that prophylactic incisional irrigation with aqueous PVP-I solution has a significant benefit on the SSI rate, particularly in clean and clean-contaminated wounds. No dose-response effect was detected. Referring to incisional irrigation with saline, evidence of moderate to very low quality shows a significant effect on SSI rate when applied with force or using pulse pressure, but not with regular irrigation. There is no significant benefit to the use of antibiotic solutions for prophylactic incisional wound irrigation or for the use of pIOWI in the abdomen or mediastinum [19].

The most commonly used irrigation solution is saline followed by aqueous PVP-I or antibiotic solutions [68, 69, 70]. The efficacy and clinical safety of irrigation with these solutions has been the subject of debate [19, 71, 72].

Wound irrigation using aqueous chlorhexidine (CHX) may be an alternative when extrapolating the favourable results from alcohol-based CHX used for pre-operative skin preparation, but clinical data are lacking. The results of aqueous 0.05% chlorhexidine gluconate as a wound irrigation fluid in the laboratory and animal studies are promising [19, 73, 74].

Charles E. Edmiston Et al. they considered the CHG (chlorhexidine gluconate), as other alternative to wound irrigation, and they consider ... A new focus for the use of CHG in surgical patients involves irrigation of the wound prior to closure with 0.05% CHG followed by saline rinse. Recent laboratory studies suggest that, following a 1-minute exposure, 0.05% CHG produces a >5 -log reduction against selective health care-associated pathogens and reduces microbial adherence to the surface of implantable biomedical devices [75].

STATEMENTS OF DIFFERENT SCIENTIFIC SOCIETIES ABOUT WOUND IRRIGATION

World Health Organization

- The panel considers that there is insufficient evidence to recommend for or against saline irrigation of incisional wounds before closure for the purpose of preventing SSI [57]

- The panel suggests considering the use of irrigation of the incisional wound with an aqueous PVP-I solution before closure for the purpose of preventing SSI, particularly in clean and clean-contaminated wounds [57]
- The panel suggests that antibiotic incisional wound irrigation before closure should not be used for the purpose of preventing SSI. (*Conditional recommendations/low quality of evidence*) [57]

Centers for Disease Control and Prevention. Guideline for the Prevention of Surgical Site Infection, 2017

- 9A. Consider intraoperative irrigation of deep or subcutaneous tissues with aqueous iodophor solution for the prevention of SSI. Intraperitoneal lavage with aqueous iodophor solution in contaminated or dirty abdominal procedures is not necessary. (Category II—weak recommendation; moderate-quality evidence suggesting a trade-off between clinical benefits and harms.) [76]
- 10. Randomized controlled trial evidence was insufficient to evaluate the tradeoffs between the benefits and harms of repeat application of antiseptic agents to the patient's skin immediately before closing the surgical incision for the prevention of SSI. (No recommendation/unresolved issue) [76].

World Health Organization. Global Guidelines for the Prevention of Surgical Site Infection

Saline wound irrigation: There is insufficient evidence to recommend for or against saline irrigation of incisional wounds for the purpose of preventing SSI [77].

Povidone iodine irrigation: Consider the use of irrigation of the incisional wound with an aqueous povidone iodine solution before closure for the purpose of preventing SSI, particularly in clean and clean-contaminated wounds [77].

Antibiotic irrigation: Antibiotic incisional wound irrigation before closure should not be used for the purpose of preventing SSI [77].

There are a homogeneous consensus, however still a lack of randomized trials in the actual literature.

GENERAL CONCLUSION

High-quality evidence from future RCTs using standardized outcome parameters is awaited urgently to clearly establish the role of IOWI in abdominal surgery on an evidence-based level in order to encounter the substantial problem of this huge health care burden worldwide [16].

Wound irrigation remains controversial as a means of reducing the risk of SSI. There is little information to suggest that routine low-pressure washing of an incision with saline reduces the risk of SSI [78], but high pressure (i.e., pulse-irrigation) may be beneficial [79].

An increasing body of knowledge suggests that topical antibiotics placed into the incision during surgery can minimize the risk of SSI [80, 81], but it might be desirable to accomplish the same result with topical antiseptics rather than antibiotics to minimize the possibility of the development of resistance [18].

Josie Chundamala et al. In their conclusions they said:

In conclusion, the evidence suggests that povidone-iodine irrigation may be effective in preventing surgical site infection. However, more studies, especially double-blind RCTs, should be conducted to determine the “ideal” solution of povidone-iodine irrigation as well as specific risks associated with its use [82].

CONCLUSION

In our experience, we consider that the irrigation of the wound with saline solution plays a role for intraoperative cleaning the wound of detritus, residual material, fibrine, clots or even intraluminal gastric or intestinal content. However, there is insufficient evidence to support its isolated use for prevention of SSI. The wound irrigation with a pvp-i solution has demonstrated more evidence as preventive measure, mainly in clean or clean-contaminated procedures. In more contaminated areas, there is not enough evidence to establish a strong recommendation, but it makes sense to apply this measure also in contaminated or dirty surgeries, as it may only represent a benefit. There is no evidence of adverse effects or development of bacterial resistance associated with its use.

On the other hand, we do not recommended the addition of antibiotic in the solution for irrigation. Actual evidence has demonstrated that antibiotics do not imply a further reduction in SSI rate than that of pvp-i solutions, and represent a risk for development of bacterial resistances. There is some evidence that topical antibiotic may be beneficial in obese patients, but further studies must be conducted to clarify this item.

In conclusion, volume, pressure and addition of drugs are items that still remain controversial. More randomized trials in these issues are necessary to get more evidence-based experience.

ABSTRACT

Peritoneal irrigation achieves a reduction in bacterial contamination. The addition of antibiotics has shown some benefits in experimental studies, but human ones have obtained controversial results. The evidence about the use of antiseptics is limited.

In this chapter we will review the available evidence.

Keywords: peritoneal irrigation, antibiotic, surgical-site infection

INTRODUCTION

Peritoneal lavage has been adopted by many surgeons for use in abdominal operations. This lavage usually consists of peritoneal irrigation with a variable volume of 0.9% sodium chloride (normal saline). The effects of lavage have been widely studied for management of patients with bacterial peritonitis, although the appropriate volume and carrier remain unclear, as does the benefit of including antibiotics or antiseptics. To reduce the morbidity and mortality of intraabdominal infections, surgeons aim to isolate and control the source of contamination. Lavage has been proposed to remove bacterial contamination and other materials that may promote bacterial proliferation (e.g., blood) and proinflammatory cytokines that may enhance local inflammation. Therefore, flushing the peritoneal cavity may reduce the bacterial load, inhibit bacterial proliferation, and possibly minimize peritoneal adhesions. Antibiotics may be combined with the lavage to further reduce bacterial survival. Antibiotics used have included metronidazole, gentamicin sulfate, cephalothin, lincomycin,

* Corresponding Author's Email: jruiztovar@gmail.com.

† Carolina Llaveró, RN.

kanamycin, doxycycline, and ampicillin. Nearly all of the previously reported studies were conducted in peritonitis situations, and most of them were under experimental conditions and stated that antibiotic lavage was safe. However, the efficacy of the lavage was not always demonstrated, especially when comparisons were made with historic controls.

Clearly, the efficacy of peritoneal irrigations in peritonitis is unclear. The concept of lavaging a contaminated or infected peritoneal cavity makes good sense intuitively. However, because microbes adhere to mesothelial cells, it is very difficult to wash them off the peritoneal surface. During fecal contamination of the peritoneal cavity, it has been demonstrated that bacteria that adhered to the mesothelium were resistant to intraperitoneal lavage, resulting in only transitory reductions of bacterial populations. Peritoneal irrigation with normal saline is not sufficient to eliminate all fecal contamination produced during the surgical act. The results obtained after antibiotic lavage defend the hypothesis that the topical effect of the antibiotics could completely inhibit the growth of bacteria in the peritoneum, even when microorganisms have adhered to the mesothelial cells. Diverse antimicrobial drugs have been used in different studies, most of which were peritonitis cases.

The results obtained are contradictory. Some authors have presented similar mortality and intra-abdominal infection rates compared with normal saline irrigation; others have shown antibiotic lavage to protect against intra-abdominal infection and reduce the mortality rate by up to 65%. A meta-analysis clearly shows the superior value of antibiotics in lavage during experimental peritonitis compared with saline lavage. Although including antibiotics in lavage solutions optimizes survival in peritonitis, the use of simple saline irrigation is still better than no lavage, rejecting the classical affirmation that irrigation contributes to contamination spread throughout the peritoneal cavity.

Peritoneal lavage with a single antibiotic drug is probably sufficient to impair the growth of some, but not all, bacterial colonies. Previous studies have not specified which microorganisms survived after antibiotic lavage. Logically, bacterial growth cannot be impaired by antibiotics to which the microorganisms are resistant.

Tolhurst Cleaver and colleagues reported that intraperitoneal antibiotic lavage accelerated wound healing and reduced the infection rate. Diverse factors contribute to the occurrence of wound infection, but infections arising from a contaminated peritoneal cavity are particularly common, indicating that wound infection rates are higher after a contaminated operation than after a clean one.

Qadan et al., noted that extrapolating results from animal models of peritonitis and antibiotic lavage to human disease is often disappointing, because in experimental peritonitis, the interval between the onset of peritonitis and the start of the lavage treatment is usually only 1 or 2 hours, which is not representative of the clinical situation (characterized by a longer time interval). A long interval between the onset of peritonitis and treatment leads to exponential growth of the microorganisms. In this situation, an antibiotic lavage would not be sufficient to control such concentrations of microorganisms but may be sufficient for lower concentrations of bacteria. Thus, peritoneal irrigation with antibiotic solutions has more sense as a prophylactic measure in elective surgery, rather than as treatment in peritoneal cases.

PROPHYLAXIS OF SSI WITH ANTIBIOTIC PERITONEAL IRRIGATION

In 2012, our group conducted a prospective randomized clinical trial, analyzing the peritoneal irrigation with normal saline (Group 1) vs the irrigation with a clincamycin-gentamicin solution (Group 2), on SSI after elective colorectal surgery. Inclusion criteria were a diagnosis of colorectal neoplasms and plans to undergo an elective operation with curative aims. An open surgical approach was used in all the patients included. Exclusion criteria were a preoperative diagnosis of chronic renal failure (because of the risk of nephrotoxicity associated with intraperitoneal gentamicin absorption) or an anastomotic leak in the postoperative course, which would represent a bias in the diagnosis of intra-abdominal infection. A CT scan with a rectal contrast enema was performed either on the fifth day after surgery or earlier if there was a strong clinical suspicion of an anastomotic leak. This procedure identified anastomotic leaks presenting as intra-abdominal abscesses rather than peritonitis.

Perioperative systemic antibiotics (ciprofloxacin 400 mg and metronidazol 1,500 mg; single dose preoperatively, within 30 minutes of incision, and redosed after 4 hours when the surgery is prolonged over that time) were used in both groups. No mechanical bowel preparation took place in any patient.

A total of 108 patients were included in the study. Five patients were excluded because they presented an anastomotic leak. In total, 51 patients were analyzed in Group 1 and 52 in Group 2. The patient sample consisted of 62% men and 38% women, with a mean age of 69.9 years. The preoperative diagnosis was adenocarcinoma in all patients. There were no differences in comorbidities and tumor stages between groups. Tumors were located in the right colon (17%), the transverse colon (3%), the left colon (50%), and the rectum (27%). In 3 patients, 2 synchronic neoplasms were detected in different locations of the colon. There were no significant differences in the surgical techniques between groups. Anastomosis was performed in 70% of the patients, leaving a terminal stoma in 30%. There were no significant differences in the distribution of patients with stomas between groups.

Anastomotic leaks appeared in 5 patients (5%), including 3 patients in Group 1 and 2 patients in Group 2 (nonsignificant, NS). Mortality was 3%, affecting 2 patients in Group 1 and 1 patient in Group 2 (NS). Causes of mortality were an anastomotic leak and sepsis in 2 patients and nosocomial pneumonia in 1 patient. Median hospital stays were 6 days (range 5 to 32 days) in Group 1 and 6.5 days (range 5 to 14 days) in Group 2 (NS).

The wound infection rates were 14% in Group 1 and 4% in Group 2 ($p = 0.009$; [odds ratio]OR4.94;95%CI 1.27 to 19.19). There was no significant association between any of the comorbidities and wound infection. Intraabdominal abscess rates were 6% in Group 1 and 0% in Group 2 ($p = 0.014$; OR 2.14; 95% CI 1.13 to 3.57). All abscesses were smaller than 4 cm and therefore were conservatively managed without requiring percutaneous drainage, so we could not obtain a sample of them for culture.

Microbiologic samples were obtained only from patients assigned to Group 2. The culture of sample 1 (before any lavage) was positive in 68% of the cases. Detected microorganisms were *Escherichia coli* (*E coli*) (94% of the samples),

Streptococcus spp (27%), *Enterococcus faecalis* (9%), *Pseudomonas aeruginosa* (6%), and *Klebsiella spp* (3%). The culture of sample 2 (after lavage with normal saline) was positive in 59% of the cases, and the same microorganisms identified in the culture of sample

1 were found in the culture of sample 2. The culture of sample 3 (after lavage with the antibiotic solution) was positive in 2 patients (4%). Detected microorganisms were *Klebsiella spp* and *Streptococcus salivarius*. The antibiogram of these microorganisms revealed that they were both resistant to gentamicin and clindamycin. There was no significant difference between the infection rates of samples 1 and 2 ($p = 0.162$). However, when comparing samples 1 and 3 and samples 2 and 3, a significant difference in the infection rate was observed ($p = 0.001$ in both cases).

The prophylactic effect of lavage in elective clean contaminated surgery is understood even less than in peritonitis because few such studies have been conducted, apart from our one. In our study, we showed that an antibiotic lavage is very effective. We demonstrated that an antibiotic lavage impairs microbiologic growth and reduced the positive culture. These data have clinical correlations because the intra-abdominal infection rate was reduced from 6% in Group 1 (only saline lavage) to 0% in Group 2 (saline lavage followed by antibiotic irrigation). Our study presents 2 main differences with the reported literature. First, our sample included patients undergoing elective colorectal surgery (contaminated surgery), but who did not present with peritonitis, as described in most reported studies. A limited number of outdated studies have analyzed the effect of prophylactic peritoneal lavage on postoperative infection. Such studies have shown a reduction in the number of aerobic and anaerobic bacteria in the peritoneal fluid after an intervention that included irrigation with a tetracycline solution, but they have not correlated these data with clinical variables. The second main difference in our study is the combination of antibiotic drugs (gentamicin and clindamycin). These 2 drugs present a synergistic effect and provide wide-spectrum protection against Gram-negative and anaerobic microorganisms, which represent the main flora of the colon.

In our study, we also observed a significant reduction in wound infections in the group undergoing an antibiotic lavage, compared with the group undergoing saline irrigation. These data show that when the peritoneal cavity remains sterile, there is a lower risk of bacteria migrating from the abdominal cavity through the fascia to the subcutaneous tissue. As in the 2 patients with positive cultures after antibiotic lavage, the same bacteria found in the culture were also responsible for the wound infection.

Figure 1. Peritoneal contamination before any lavage (Sample 1), after irrigation with normal saline (Sample 2) and after irrigation with antibiotic solution (Sample 3).

The conclusion of this study was that antibiotic lavage of the peritoneum before abdominal wall closure is associated with a lower incidence of intraabdominal abscesses and wound infection. Microbiologic cultures of the peritoneal surface at the end of an elective colorectal operation were positive in 68% of the cases. A normal saline lavage did not significantly reduce the number of positive cultures, in contrast to an antibiotic one (gentamicin-clindamycin), which resulted in negative cultures for all sensitive microorganisms. This study would support the use of antibacterial peritoneal irrigation as prophylactic measure against SSI. Moreover, the main criticism of the use of topical antibiotics is the development of eventual resistant microorganisms against the drugs used. In our opinion, the antibiotics used should be those ones not usually employed for treatment aims. In our study we used clindamycin, which is not a drug currently used for the treatment of intra-abdominal infections, and despite gentamicin is frequently used for the treatment of gram-negative infections, it is true that there are other more powerful aminoglycosides for treatment uses, and even gentamicin is included in many systemic prophylaxis protocols. Further studies must be conducted to confirm these hypotheses.

Topical Peritoneal Irrigation with Antiseptic Agents

Antiseptic agents, such as Polyvinylpyrrolidone (Iodine Povidone) or Chlorhexidine have demonstrated an antibacterial effect and are currently used for topical antisepsia of skin or mucosae. However, the peritoneal surface has the characteristic of absorption and this limits the applicability of several drugs to this surface.

Experimental studies with peritoneal Povidone irrigation have demonstrated a significant reduction of SSI. Povidone irrigation reduces the permeability of the mesothelium to bacteria and, consequently might reduce the systemic spread of the microorganisms.

Studies on human have been conducted on patients with peritoneal carcinomatosis, aiming to reduce the tumoral load. However, this topical administration has shown a certain peritoneal absorption and may lead to systemic toxicity. Moreover, several patients developed sclerotic peritonitis. Thus, peritoneal Povidone administration is actually not recommended.

Peritoneal irrigation with Chlorhexidine has also demonstrated in experimental studies a significant reduction of bacterial contamination. However, an important chemical irritation was also observed, leading to extensive inflammatory response. Long-term follow-up of these patients has shown the development of peritoneal adhesion and bowel obstruction. However, the latter has not been confirmed in recent animal studies. Thus, the role of topical Chlorhexidine in peritoneal irrigations must be further elucidated.

CONCLUSION

Peritoneal irrigation achieves a reduction in bacterial contamination. The addition of antibiotics has shown some benefits as prophylactic measure against SSI. However, there is still not enough evidence to be a recommended measure by scientific societies. Povidone and Chlorhexidine solutions seem to be associated with greater adverse events than benefits and are actually not recommended for peritoneal irrigation.

Chapter 281

PROPHYLACTIC VACUUM THERAPY

Montiel Jiménez-Fuertes*

General and Digestive Surgery, Rey Juan Carlos University Hospital,
Madrid, Spain

ABSTRACT

Surgical site infections are an important complication after surgery, affecting the quality of life and the economic cost. It is important to note that infections are multifactorial, involving both surgical and patient factors. To decrease the occurrence of infections, surgeons frequently use several tools to reduce the incidence of them. Strategies that prevent surgical site infection (SSI) are increasingly important and current literature suggests that incisional Negative Pressure Wound Therapy (iNWPT) is a promising intervention.

Keywords: negative pressure wound therapy, prophylaxis, incision management, surgical-site infection

INTRODUCTION

Surgical site infections (SSI) are the most common cause of nosocomial infection, because they are the 38% of all hospital-acquired infections. Though the overall incidence of SSI is low, the highest rates occur after abdominal surgery [1].

Surgical site infections (SSI) are categorized as superficial incisional, deep incisional, and organ/space based on the depth of the infection, they can increase healthcare costs by approximately \$20,000 per admission, and add an average of 10 days of length-of-stay [2]. Given this effect on patient outcomes and costs, much work has been done to develop interventions that can decrease the rate of SSI. The most data have been produced in the fields of colorectal, gynecology, and urology which involve manipulation of the gastrointestinal or genitourinary systems; or in fields in which placement of prostheses require all effort to

* Corresponding Author's Email: montiel.jimenez@hospitalreyjuancarlos.es.

reduce SSI, such as orthopedics, neurosurgery and cardiothoracic. There have been many skin closure adjuncts employed to reduce SSI, pre-closure, wound irrigation, and some are post-closure such as topical antibiotic agents and incisional negative pressure wound treatment (iNPWT) applied to a closed incision. All, however, remain debatable as to their efficacy despite having been studied in many surgical settings.

Incisional Negative Pressure Wound Treatment

Incisional negative pressure wound treatment (iNPWT) has emerged as a useful tool to reduce surgical site infections (SSIs) [3]. INPWT technology has been developed like Prevena™ (KCI USA, Inc., San Antonio, TX) and Pico (Smith & Nephew Inc, Andover, MA) systems. Both have been created to develop prophylactic measures to prevent complications via application immediately after surgery in high-risk closed surgical incisions. NPWT involves the controlled application of continuous sub-atmospheric pressure to the wound. While NPWT technology is an established and accepted treatment for non-healing wounds and open surgical incisions following infection, a small but growing number of clinical studies have been published based on the hypothesis that negative pressure dressings improve healing of closed wounds.

Figure 1. Prevena™ Incision Management system: 1: closed wound; 2-11: customizable prevena placemet step by step; 12: final view with de dressing working.

Prevena™ Incision Management system consists of a vacuum therapy suction unit that is connected to a dressing tube by a canister for fluid collection, and a precut peel-and-place reticulated open-cell foam dressing specifically designed for use over closed surgical incisions that are at high risk for post-surgical complications (*Figures 1 and 2*). The dressing has a plated non-adherent layer surrounding the foam and a semi-permeable adhesive drape.

Pico systems is canister-free, the pump generates a negative pressure of -80 mmHg (for 7 days of therapy) and is connected to a dressing that manages the fluid away from the wound or closed incision through a unique combination of absorbency and evaporation.

An increased understanding of the science behind incisional NPWT and its effects on wound and periwound tissue is essential to expand the use of incisional NPWT. Well-described mechanisms of action of incisional NPWT include protection of the incision site from external infectious sources and help in holding incision edges together [4]. Incisional NPWT also removes fluids and infectious materials from the surgical site, which is especially important in critical anatomical locations. Other mechanisms of action, particularly at the cellular and molecular level, are less understood and the subject of ongoing research [5].

Figure 2. Prevena™ Incision Management system. A: Abdominal closed wound; B: Prevena™ in place and working.

EFFECTS OF INCISIONAL NEGATIVE WOUND PRESSURE DRESSING IN WOUNDS

Surgical incisions disrupt the cutaneous layer that normally doesn't let bacteria entering the body. In healthy people it takes three to six days for reepithelialization to restore the barrier function of the skin. Risk factors such as diabetes or contaminated surgical fields such as related to abdominal surgical procedures with intestinal anastomoses result in prolonged time to healing [6]. Post-operative colonization of surgical sites is associated with increased risk of SSI [7].

NPWT's ways to prevent SSIs includes completely eliminating dead space, removing fluid and blood, improving blood flow and preventing the formation of subcutaneous seromas/hematomas that become secondarily infected. In addition, INPWT is thought to decrease local inflammatory response and cell death by increasing the oxygen gradient across a wound.

The NPWT dressing is applied to the surgical site under sterile conditions, after which a continuous amount of sub-atmospheric pressure is applied for several post-operative days. Most studies report use of - 80 or -125mm Hg of sub-atmospheric pressure, for a length of five to seven days after operation.

Jansen et al. [5] demonstrated a correlation between external negative pressure applied by the iNPWT system and the pressure within the wound. Even low external negative pressure (about 50 mmHg) led to relevant negative pressure within the wound.

Barrier Function of NPWT

Because of its non-occlusive nature, gauze and other dressings are permeable to bacteria [8]. Lawrence et al. [9] have demonstrated that bacteria can pass through up to 64 layers of dry gauze in a *in vitro* study. In contrast, iNPWT uses a foil that is impermeable to pathogens. INPWT devices have the ability of the dressing to serve as a barrier against external contamination, and this was verified through a Phi-X 174 bacteriophage challenge. This test indicated that there was no pathogen penetration through the foil [10]. Moreover, the subatmospheric pressure results in close approximation of the foil to several centimeters of skin, while also approximating both incisional edges. Anything that passes through the incision is also directed away from the surgical site as a result of the direction of suction, and in this way it acts as a barrier against external bacteria. This is in line with the clinical results of Grauhan et al. [11], who have found that iNPWT resulted in a significant reduction of SSI from (grampositive) skin flora after cardiac surgical procedures in obese individuals (1/75 vs. 10/75, $p = 0.009$). Moreover, because an iNPWT dressing commonly is left in place for 7 days, less dressing changes [12] and bedside examinations take place, and by decreasing the exposure of the surgical site to potential colonization from the nurses.

Seroma, Hematoma and Edema Reduction

Seroma development is one of the most commonly reported complication, and both are associated with an increased risk of SSI [13]. Hematomas and seromas result from the accumulation of blood and serum, respectively, in internal spaces. Even with an excellent surgical technique, bleeding, inflammation and serum extravasation may occur, resulting in increased probability of infection, slower healing, additional clinic visits and surgical re-interventions.

In vivo studies have provided evidence of improved fluid flow with four days of continuous INPWT (Prevena™ Incision Dressing) under -125 mmHg over clean, closed incisions, showing that its application, when compared with semi-permeable film dressing (Tegaderm™ Dressing, St. Paul, MN, USA), significantly decreased the amount of porcine subcutaneous dead spaces beneath superficial closed incisions indicating reduced

haematoma/seroma [14]. In humans, there are several randomized controlled trials, of which several reported decreased seroma and hematoma formation, but there are others that didn't see this effect [15-19].

Edema has a detrimental effect in wound healing because of the increased diffusion distance for oxygen, and the oxygen is important for bacterial clearance [20]. It has been suggested that iNPWT is effective at reducing edema, which increases tissue oxygenation and thereby bacterial clearance [21].

Effect of iNPWT on Perfusion and Necrosis

A good perfusion and oxygenation are essential for a good surgical site healing. In the first animal study on NPWT, Morykwas et al. [22] have shown that the cutaneous application of NPWT onto ischemic skin flaps made a significant reduction of cutaneous necrosis in their porcine model. Correspondingly, cutaneous application of NPWT results in a perfusion increase when applied to intact skin of healthy volunteers [23], and in significantly increased perfusion at post-operative days four, seven, and 21, as measured with laser Doppler perfusion imaging [24-25].

Wound Dehiscence

The biomechanic effects of iNPWT on closed wounds have been evaluated with computer models and they showed that iNPWT reduces the lateral distraction force in wounds [26], and this is important because a wound dehiscence increases the risk of SSI due to bacteria contamination.

SSI

iNPWT seems to be effective in the prevention of SSI acting as a barrier which avoids bacteria contamination of the wound before healing, improving the lymphatic and blood flow, reducing seroma, hematoma, edema and wound dehiscence. This suggests that iNPWT is a favorable prevention strategy to consider. This is substantiated in part by the clinical data available, as assessed in meta-analyses that show that iNPWT reduces SSI [1]. This suggests that iNPWT is effective in reducing the risk of SSI in all types of surgical procedures, and likely even in the types of operations where no clinical data exist yet. Because of these results, the World Health Organization recommends to consider iNPWT for all high-risk surgical sites [27].

CONCLUSION

iNPWT is an effective intervention as the result of its barrier function and optimization of the wound microenvironment. Incorporation of iNPWT in SSI prevention bundles is recommended supported by the data available in this moment.

Chapter 282

ANTIMICROBIAL SUTURES

Jaime Ruiz-Tovar¹, MD, PhD and Carolina Llaveró^{2,*}

¹Center of Excellence for the Study and Treatment of Obesity
and Diabetes, Valladolid, Spain

²Department of Surgical Nursery, Sureste Hospital, Madrid, Spain

ABSTRACT

The suture used for the aponeurotical closure might influence in the incidence of surgical-site infection (SSI). Microorganisms adhere to the suture material, specially in multifilament ones, and can show a relevant proliferation far away from the action of prophylactic systemic antibiotics. The use of sutures embebbed with antiseptic agents has demonstrated to reduce the incidence of incisional SSI.

The aim of this chapter is to review the actual evidence about this issue and to show the most relevant recommendations of several scientific societies.

Keywords: antimicrobial sutures, triclosan-coated sutures, surgical site infection

INTRODUCTION

Surgical-site infection (SSI) is one of the most frequent complications of abdominal surgery. It is associated with prolonged hospital stay, reduction of quality of life and increases of morbidity, mortality and sanitary costs. The reported incidence of SSI depends, among other factors, on the definition of SSI. The Centers for Disease Control (CDC) define SSI as the infection appearing in the surgical incision or close to it, during the first 30 days after surgery, or up to 3 months postoperatively, when a prosthesis has been placed. SSI occurs when the bacterial inoculum overcomes the ability of the immune system to control it. The bacterial contamination in abdominal surgery comes from the skin and the target organs during the surgical intervention.

* Carolina Llaveró, RN.

The determinants of infection are the surgeon, the pathogen and the patient. The surgeon is the main modulator of surgical infection. Its experience and ability might reduce the inoculum to small dimensions, amenable to be controlled by the host defenses. A correct surgical act comprises a careful management of the tissues, a correct hemostasis, to avoid unnecessary prolongations of the surgical act and to minimize the exit of intraluminal content. Factors depending on the patient include comorbidities, obesity, tobacco habit and elderly. During the last decades, the pattern of microorganisms causing the infection has not changed, but the rate of resistant microorganisms.

The surgeon has pharmacological and non-pharmacological measures to reduce bacterial contamination from the surgical field and consequently the incidence of SSI. During the last decade, the use of bundles has become popular, as groups of systematic measures used for the prevention of postoperative complications. These bundles have been especially popular in colorectal surgery, which are considered high-risk procedures for infectious complications. In 2004, the CDC began the *Surgical Infection Prevention Project* (SIP), to assure the follow-up of several basic evidence-based measures for SSI prevention (adequate use of antibiotic prophylaxis, its administration 1h before skin incision and stop before 24h after surgery, appropriate hair removal and maintenance of normothermia). When applying these measures, Hendrick et al. reported in 2007 a better implementation of the prophylaxis protocol and a SSI reduction from 25.6% to 15.9% in colorectal surgery. However, a similar study did not confirm these findings, despite an improvement in all the aspects of the prophylaxis process. In 2011, a randomized study of 211 colorectal surgeries compared the implementation of a classic bundle with a bundle including, avoidance of mechanical colon preparation and oral antibiotic administration. Despite improvements in the implementations were observed, an increase in SSI rate from 24% to 45% was detected. In Spain, a multicentric observational study, analyzing the incidence of SSI in colorectal surgery, with implementation of a bundle similar to that from the SIP project, obtained a SSI rate of 23.1% in 611 colorectal interventions.

In conclusion, the adoption of bundles of evidence-based preventive measures against SSI lead to an improvement in the surgical process. The adhesion to the bundles by means of a check-list has shown to reduce SSI rates. However, there are still unknown factors implied in the development of SSI, that must be further investigated.

SUTURES EMBEDDED WITH ANTISEPTIC AGENTS

The use of sutures coated or embedded with antiseptics are preventive measures against SSI, that can be implemented by the surgeon. Several studies has demonstrated that the suture used for the aponeurotic closure is a relevant factor that might influence the incidence of SSI. Bacteria adhere to the filaments of the suture, especially in multifilament ones. Thus, monofilament sutures are widely recommended for fascial closures, as with these sutures there is a lower place for bacterial accommodation.

In abdominal surgery, bacterial contamination comes from the digestive tract (*Enterobacteriaceae* and anaerobic microorganisms) and from the saprophytic flora of the skin (grampositive). Sutures coated with antiseptic agents were designed to form a barrier against the bacterial transit from the intraperitoneal cavity to the subcutaneous tissue, that might lead

to the development of incisional SSI. Moreover, their bactericide effect would prevent from bacterial adhesion to the suture filaments.

The most employed antiseptic agent used to coat the sutures is Triclosan (2,4,4-trichloro-2-hydroxy-diphenyleter). In preclinical studies, Triclosan has demonstrated to reduce the bacterial load in the wound and to slow bacterial growth, inhibiting the synthesis of bacterial fatty acids.

Triclosan-coated sutures have been analyzed in different surgical procedures in humans, though most of them were conducted in clean and clean-contaminated ones. Among them, colorectal surgery has been the most widely procedure investigated, as the high incisional SSI rates that present, make these approaches as the most amenable to perform investigations on them. However, Triclosan-coated sutures have also demonstrated their efficacy in dirty surgery. A previous study of our group evaluated the efficacy of Triclosan-coated sutures in fecal peritonitis, revealing that the use of these sutures might reduce the incidence of incisional SSI in up to 80%.

Evidence

Up to date, 10 meta-analyses have been published, evaluating the efficacy of Triclosan-coated sutures, demonstrating all of the a reduction in SSI rates, ranging from 24% to 84%.

Wang et al. were the first who published a systematic review and meta-analysis on Triclosan-coated sutures in 2013. They included 17 clinical trials and 3720 patients were enrolled. Triclosan-coated sutures showed a 30% reduction of SSI. Subgroup analyses revealed homogeneous results in adults, abdominal procedures, and clean and clean-contaminated procedures.

The same year, Sajid et al. conducted a systematic review of clinical trials evaluating the effect of antibacterial sutures on skin closure. Seven studies with 1631 patients were included. They concluded that Triclosan-coated sutures reduced the SSI rate, but a significant reduction of hospital stay could not be observed.

Edmiston et al. performed a systematic review of 13 clinical trials with 3668 patients, showing that the use of antibacterial sutures was associated with a 31% global reduction of SSI, but it can reach up to 47% in selected populations.

The same authors published the next year a new systematic revision, including more rigorous methodology and updated the results with 2 additional clinical trials (totally 15 clinical trials and 4800 patients). They concluded that the use of Triclosan-coated sutures reduced the SSI risk in 33%. Depending on the degree of contamination, they observed that the risk reduction was applicable to clean, clean-contaminated and contaminated procedures, with evidence grade 1A.

In 2015, Apisarnthanarak et al. published a systematic review, including 22 clinical trials and 7 non-randomized studies. A 26% reduction of SSI risk was observed among clinical trials and a 47% reduction among non-randomized studies. In abdominal surgeries a 44% reduction was determined.

Guo et al. published in 2013 a meta-analysis of 13 clinical trials with 5256 participants. They performed a subgroup analysis based on the type of suture (Polyglactine 910 or Polydioxanone), coated or not with Triclosan. Globally, coated sutures were associated with a 24% lower risk of SSI. Depending on the type of surgery, the SSI risk was reduced a 30% in

abdominal surgery within the patients undergoing Triclosan-coated sutures, but significant differences were not established in cardiac, mammary or other extra-abdominal procedures. The beneficial effect was determined both with the use of Triclosan-coated Polyglactine or Polydioxanone sutures, when compared with their corresponding Triclosan-free sutures. SSI reduction was associated with reduction of hospital stay and sanitary costs.

In 2017, Wu et al. performed a meta-regression analysis to determine if the effect of Triclosan varies depending on the type of suture or procedure. They included 13 clinical trials and 5 observational studies. Triclosan-coated sutures presented a 28% lower SSI rate among clinical trials and 42% lower risk among observational studies. The effect of the Triclosan coat was similar in the different types of sutures and procedures. The quality of evidence was moderate.

De Jonge published a 39% reduction of SSI risk with the use of Triclosan-coated sutures, after analyzing 21 clinical trials and 6462 patients.

Leaper et al. analyzed the clinical and economic impact of the use of these sutures. They analyzed 34 studies. Despite the incisional SSI rate was lower with the use of Triclosan coated sutures, the reduction was more pronounced in contaminated and dirty procedures. A 39% SSI reduction was estimated implying a mean sanitary cost reduction of 105€ per procedures among all types of surgeries, with 65€ reduction in clean surgeries and 285€ in contaminated or dirty ones.

In contrast, the meta-analysis of Konstantelias et al., including 30 studies, 19 of the clinical trials, and more than 15000 patients, observed that the use of Triclosan-coated sutures was associated with lower SSI risk in clean, clean-contaminated and contaminated procedures, but not in dirty ones. Specifically in colorectal surgery, they determined a reduction of 42% in the risk of SSI development. Moreover, a lower risk of wound dehiscence was also observed.

RECOMMENDATIONS OF SCIENTIFIC SOCIETIES

Based on all this scientific evidence, diverse organizations and societies have published recommendations, supporting the use of Triclosan-coated sutures.

World Health Organization (WHO)

In the paragraph 4.22 of the WHO recommendations for SSI prevention, the panel of experts recommend the use of Triclosan-coated sutures to reduce SSI, independently of the type of surgery. Evidence was cataloged as moderate. The effect seems to be independent from the type of suture (monofilament or multifilament), surgical procedure and wound contamination.

To establish this recommendation, 13 clinical trials and 5 observational studies were analyzed, including more than 7400 patients, comparing Triclosan-coated vs conventional sutures. The recommendation established by the WHO is considered conditional, as coated sutures are more expensive and their availability is limited in many countries. However, the uses of Triclosan-coated sutures might reduce mean hospital stay and, consequently, sanitary

costs. They mentioned the possibility of development of resistances as a worrisome issue, but the daily absorption of Triclosan in many products, such as hand soap, is superior to that associated to a Triclosan-coated suture.

Centers for Disease Control and Prevention (CDC)

In the paragraph 2C, within the non-parenteral antimicrobial prophylactic measures, the use of Triclosan-coated sutures is included (Category II, low recommendation grade, moderate evidence). The evidence suggests that benefits compensate prejudices. No benefit was observed for the prevention of organ/space SSI.

This recommendation was based on the analysis of 14 randomized controlled studies, including 5388 patients.

There is no evidence of antimicrobial resistances, adverse events or wound dehiscence.

American College of Surgeons and Surgical Site Infection Society

Historically, Triclosan-coated sutures were not recommended for SSI prevention, but actually there is enough evidence to support their use. Diverse studies have demonstrated a lower risk of SSI development with their use, when compared with standard sutures, including multiple clinical trials. Additionally, systematic reviews and meta-analysis have confirmed this effect.

Thus, these societies recommend the use of antibacterial sutures, but with 2 conditions:

- They must be used exclusively for the suture of aponeurotic layers, subcutaneous tissue and skin in abdominal surgeries, but their use is not justified for visceral sutures.
- The contamination grade must be clean or clean-contaminated. There is not enough evidence to justify their use in contaminated or dirty procedures.

Chapter 283

WOUND COVER: TOPICAL ANTIBIOTICS OR ANTISEPTICS

Helen Almeida Ponce* and Pablo Royo Dachary

Department of Surgery, University of Zaragoza,
Zaragoza, Spain

ABSTRACT

Wound coverage is thought to play a role on the prevention of surgical site infection (SSI). Dressings and antiseptics after surgical procedures are widely used and topical antibiotics have been studied by many authors although not included in clinical guidelines. Furthermore, combinations of these three elements are broadly available in clinical practice as an attempt to improve SSI prevention or to potentiate dressings actions on chronic or infected wounds.

Keywords: dressings, topical antibiotics, antiseptics, wounds

INTRODUCTION

In general surgery, the acceptable rate of infection following clean surgery is less than 5%, nevertheless, even within cohorts with a low overall risk of infection, some procedures may be at higher risk, and infection rates may be greater than 5% in these high-risk groups.

Wound coverage is a typical conduct throughout the world and common to all surgical and medical disciplines that involve a wound. It could be meant to protect the wound from external aggressive or contaminant agents, to add compression and avoid further bleeding, to manage exudates, to enhance the healing process or to avoid patient's traumatic reaction to the sight of their injuries. The role of wound coverage in the prevention of the surgical site infection (SSI) appears to be obvious, as it implies a physical barrier to external elements, but SSI rates remain the same, indicating that external sources are not the only element behind them and leaving an open door to other preventive actions.

* Corresponding Author's Email: helen.almeida.p@outlook.es.

Many initiatives have been suggested and tested in order to prevent or reduce surgical site infection in patients operated on for non-septic processes. In this context, antibiotic infusion is one of multiple measures used to achieve this goal, and its intravenous administration is clearly demonstrated and globalized, same as standard aseptic and antiseptic solutions to reduce the microbial contaminant exposure prior to the surgical procedure. On the other hand, wound coverage following surgical procedures, with elements such as topical antibiotics, antiseptics and dressings is still controversial, and actual guidelines do not include their systematic use after general surgery.

In this chapter we review the existing evidence on the role of wound cover in the prevention of surgical site infection.

WOUND DRESSINGS

Several attributes of an ideal wound dressing have been described according to the British National Formulary, these include: the ability of the dressing to absorb and contain exudate without leakage or strike-through, lack of particulate contaminants left in the wound by the dressing, thermal insulation, impermeability to water and bacteria, suitability of the dressing for use with different skin closure methods, avoidance of wound trauma on dressing removal, frequency with which the dressing needs to be changed, provision of pain relief, cosmesis and comfort, effect on formation of scar tissue, and transparency to aid visualisation of the wound.

Table 1 resumes the wide variety of dressings existing nowadays, as a result of their evolution towards achieving the attributes of an ideal dressing for different types of wounds, potentially improving their capacity to prevent infections, favour the healing process or bettering patients experience.

Table 1. Simplified classification of wound dressings

Wound dressing	Potential Benefits	Potential risks	Use	Considerations
Wound exposure	Allow follow-up without manipulation	Exposition to environmental contamination	Clean wounds	Some patients may not feel comfortable
Basic dressing				
Absorbent 	Simple and inexpensive. Easy to change	Risk of maceration in high exudative wounds	Common wounds	Early (<48h) versus delayed (>48h) change has demonstrated no benefit
Low-adherence 	Avoid adhesion to wound tissues	Low absorption capacity	Exposed tissues with risk of adhesion.	They are either non-medicated (e.g., paraffin gauze dressing), or medicated (antibiotics, antiseptics. etc.).

Advanced dressings				
Transparent film dressings 	Provide a moist healing ambient	Dressing changes are less frequent	Clean wounds	Won't adhere to a moist surface
Foams 	Creates a humid ambient to improve wound healing. Avoid adherence to wound	Dressing changes are less frequent	Moderate exudative wounds	Not recommended in wounds with dead spaces. Certain antiseptics may damage the foam product
Hydrocolloids 	Exudate management	Dressing changes are less frequent (every 3-7 days)	High exudative wounds	May cause peri wound maceration
Vacuum assisted 	Accelerate wound healing improving vascularization	More expensive	Complex wounds with lack of tissue	Pay attention to bowel exposure
Antimicrobial 	Active SSI prophylaxis. Skin decontamination		Potentially infected wounds	Could include antibiotics (e.g., neomycin) or antiseptics (e.g., silver)
Skin adhesives 	Act as a barrier	There is no scientific evidence of their benefits	Closure of minor skin wounds and for additional suture support	Contain enbucrilate or octyl 2-cyanoacrylate

Basic Dressings

The most frequently used dressing for clean surgical wounds. Basic dressings perfectly fulfil the mission of isolation from external elements. They are simple and inexpensive and allow daily replacements easily. They have an absorbent surface to manage small exudates.

Drawbacks are: 1. their inability to handle highly exudative wounds, which can cause maceration and hinder wound closure; and, 2. allergic reactions or blisters on the skin due to high adherence.

Low adherence basic dressings may contain agents to prevent tissue adhesion, such as vaseline. This is very useful in wounds with exposed tissues, but also greatly diminishes the ability to absorb exudates.

There is no evidence of benefits of early (once every less than 48 hours) versus delayed (once every 48 hours or more) change of basic dressings in terms of wound infection.

Advanced Dressings

They emerge as a result of the extensive research on the different characteristics and requirements of wounds, not only those produced by surgical procedures (clean, contaminated or urgent) but also chronic wounds in diabetic, malnourished, immobilized patients, etc.

The groups most commonly found on general practice and their main characteristics are described in the following section.

Transparent film dressings	
They provide a moist healing environment, protect the wound from mechanical trauma and bacterial invasion, act as a blister roof or “second skin” and they are waterproof. Because of their flexibility, they can be used in awkward locations such as joints or skin folds. Transparency makes it easy to visualize the wound bed. Although these dressings can’t absorb fluid, they’re permeable to moisture allowing one-way passage of carbon dioxide and excess moisture vapor away from the wound. They reduce manipulation as it is not necessary to replace the dressing while the wound shows no signs of infection. Some patients may not feel comfortable with wound visibility. They need healthy skin around the wound because its adhesive properties are deactivated by moisture.	
Indications	Contraindications
Partial-thickness wounds with no or minimal drainage When protection is needed for intact skin, for example, protection of bony prominences such as elbows and heels from friction To promote debridement of eschar To protect and secure I.V. catheters To secure another dressing.	Contraindicated in patients with moderate to heavy exudate, third-degree burns, suspected or active infection, fungal infection, or active herpetic lesions. These dressings can cause peri wound maceration. Not recommended for patients with fragile or thin skin, especially elderly patients, or patients receiving steroids, to avoid epidermal stripping or skin tears.
Foams	
A porous structure that can absorb fluids into air-filled spaces by capillary action. The most commonly used foam is polyurethane. Silicone foam is less frequently used as the primary absorbent in wound dressing, but it is often applied as an adhesive wound contact layer. These dressings may have variable thickness and can be adhesive or non-adhesive. They are commonly supplied with a film-backing, which has the purpose of providing a water and microbial resistant barrier to the environment. They can be used as primary dressing or secondary dressing in combination with amorphous gels applied to the wound bed to provide moisture. The hydrogels are not absorbed into the foam due to their high viscosity.	
Indications	Contraindications
Acute and chronic wounds of both partial and full thickness Medium to heavy exudate.	Certain antiseptics may damage the foam product (e.g., iodine, chlorhexidine, hypochlorite, ether, hydrogen peroxide, oxygenated water, and sodium hypochlorite)

Hydrocolloids:	
They contain gel-forming agents (a gelatine or sodium carboxymethylcellulose) held within an adhesive compound, which is laminated in place on a foam or film, generally made of polyurethane. The end product is an advanced wound dressing that resembles an absorbent, flexible wafer, typically both waterproof and self-adhering. Hydrocolloid dressings are occlusive, providing a moist healing environment, autolytic debridement and insulation. Changes should be done every 3 to 7 days depending on wound conditions and type of hydrocolloid.	
Indications	Contraindications
Non-infected wounds with scant to moderate drainage Necrotic or granular wound Dry wound Partial- or full-thickness wound Protection of intact skin or a newly healed wound.	Not recommended for wounds with heavy exudate, sinus tracts, or when infection is present Assessment can be difficult if the hydrocolloid dressing is opaque May become dislodged if the wound produces heavy exudate May curl or roll at the edges Upon removal, dressing residue may adhere to the wound bed and there may be an odour May cause peri wound maceration May cause trauma/injury to fragile skin upon removal May cause hypergranulation
Impregnated dressings	
Gauze, bandage, etc. treated with a special chemical agent that promotes increased wound healing and a generally more sterile environment. These compounds must be paired with a secondary dressing, as they are generally non-adherent to most wound beds. There are several preferred impregnating mixtures, and each one has its own use and benefits. 1. Silver impregnated dressings: silver is utilized to help reduce the spread of bacteria and other harmful contaminants. Most often, physicians will pair silver with alginate or foam dressings, which improve its bacteria-fighting capabilities. They can be used on almost any wound, including heel abrasions and various ulcers. 2. Honey impregnated dressings: Like silver, honey has broad-spectrum applications. The acid found in honey causes an uptick in oxygenation, which makes the wound bed all but inhospitable for most forms of bacteria. It's worth noting, though, that there are several different kinds of honey – like fireweed, sage and orange blossom – and each variety is uniquely potent as an antimicrobial agent. 3. Iodine impregnated dressings: This chemical is used extensively as a powerful disinfectant. Among a number of trials, iodine worked best in healing chronic ulcers and low-level burns, as the chemical was adept at destroying bacteria in these unique wound beds. 4. Methylene blue dressings: methyl blue is proven against several bacteria, including vancomycin-resistant enterococcus. This wound agent is normally paired with gentian violet which is best at combating a variety of fungal strains. Hydrofera Blue is one of the most popular dressings featuring this methyl-gentian combination. This dressing is used to treat everything, from diabetic ulcers, to wounds that come as a result of acute respiratory distress syndrome. Hydrofera Blue is noted for being more absorbent than other dressings, especially silver and foam, and doesn't hinder growth factor activity. 5. Antibiotic dressings: they are non-toxic and can work effectively on the target sites without damaging hosts tissues. Some of the most commonly used are quinolones such as ciprofloxacin, ofloxacin, levofloxacin, etc; gentamycin, doxycycline, nitrofurantoin, etc.	
Vacuum-assisted closure (VAC):	
This device decreases air pressure on the wound. This can help the wound heal faster by gently removing fluid from the wound over time, reducing swelling, favouring wound's cleansing and removing bacteria. A wound VAC also helps pull the edges of the wound together. And it may stimulate the growth of new tissue that helps the wound close. A wound vacuum system has several parts. A foam or gauze dressing is put directly on the wound. An adhesive film covers and seals the dressing and wound. A drainage tube leads from under the adhesive film and connects to a portable vacuum pump. This pump removes air pressure over the wound either constantly, or in cycles. The dressing is changed every 24 to 72 hours.	

Indications	Contraindications and risks
Highly exudative wounds that require frequent changes of other types of dressings. Wounds healing by first or second intention provided that they have no bleeding or exposed bowels	Negative pressure should not be used in wounds with active or known risk of: Bleeding Enteric fistula
Skin adhesives	
Cyanoacrylate tissue adhesives combine cyanoacetate and formaldehyde in a heat vacuum along with a base to form a liquid monomer. When the monomer comes in contact with moisture on the skin's surface, it chemically changes into a polymer that binds to the top epithelial layer. This polymer forms a cyanoacrylate bridge, binding the two wound edges together and allowing normal healing to occur below. The conversion from monomer to polymer occurs rapidly, preventing seepage of the adhesive below the wound margins, as long as the edges are well apposed. Heat is often generated during the change from monomer to polymer, and this heat may be felt on occasion by patients during application to the skin. Cyanoacrylates have also been shown to have antimicrobial properties. The adhesive acts as its own water-resistant bandage, and no added coverings are needed. Patients may shower normally and pat the area dry. The adhesive will spontaneously peel off in five to 10 days.	
Indications	Contraindications
Wounds healing on first intention Non-exudative wounds with clean edges	High risk of wound exudate or wound infection Topical antibiotics should not be applied to the closed wound for this would break down the adhesive and cause early peeling.

Studies to assess the effectiveness of dressings in the prevention of SSI have compared wound exposure to basic and advanced dressings, and basic contact dressings to advanced, antimicrobial and adhesive dressings. No recommendation based on evidence has emerged from the existing data.

Wound Cover versus Wound Exposure

It is uncertain whether there is a difference in SSI risk between basic wound dressing and wound exposure. Two trials were carried (Law in 1987 and Phan in 1993), comparing both clean and potentially contaminated surgery, with a combined total of 409 patients. No differences were found in SSI in the comparison groups. Both trials have a very low certainty evidence and a high risk of bias and their findings are summarized in Table 2.

Table 2. Wound exposure vs basic wound dressing

Author, year	Type of surgery	No.	SSI in covered vs exposed wounds	RR
Law, 1987	Clean	112	3/59 (5%) vs 1/53 (2%)	0.37 95% CI 0,4-3,46
Phan, 1993	Potentially contaminated	297	21/102 (21%) vs 29/105 (28%)	1.34 95% CI 0,82 – 2,19

In 2011, Siah et al. compared a silver dressing with wound exposure in 166 participants undergoing various types of elective colorectal surgery classified as clean/contaminated. No significant differences were found, as 8/83 (10%) in the exposed wound group developed SSI, compared with 1/83 (1%) in the silver-dressed wound group (RR: 8.00, 95% 1.02 to 62.55) with evidence of very low certainty, downgraded once for risk of bias and twice for imprecision by the Cochrane research team.

Dressings Compared with Other Type of Dressings

Many studies have been conducted comparing multiple kinds of dressings, in order to determine effectiveness in the prevention of SSI, and other characteristics such as ease of removal, effect on pain, costs, etc., but, as with other broad fields, heterogeneity in measurement scales and reported results, makes it difficult to draw conclusions.

Basic Wound Contact Dressings versus Film Dressings

Eight trials including 1089 patients (pooling all trials), compared a basic wound contact dressing with a film dressing. Five of these trials evaluated wounds resulting from 'clean' surgical procedures (Cosker 2005; De Win 1998; Law 1987; Moshakis 1984; Wynne 2004). According to the Cochrane revision on the subject, for clean surgery "*There is uncertain evidence on the risk of SSI between basic wound contact-dressed wounds and film-dressed wounds (RR 1.34; 95% CI 0.70 to 2.55); very low certainty evidence downgraded once for risk of bias and twice for imprecision.*"

Two studies evaluated wounds resulting from surgical procedures with mixed, or unclear, contamination classifications. The trials included a variety of basic wound contact dressings including gauze and surgical absorbents. Similarly, whilst the comparators were all film dressings of different brands. Table 3 summarizes the results of these two trials.

Table 3. Basic wound contact dressing versus film dressing

Author, year	Type of surgery	No.	SSI in contact vs film dressings	RR
Gardezi, 1983	Clean/contaminated	100	6/50 (12 %) vs 3/50 (6%)	0.50 95% CI 0.13- 1.89
Rohde, 1979	Unclear	90	24/46 (52 %) vs 14/44 (32%)	0.61; 95% CI 0.36 to 1.02. In favour of the film dressing.

Basic Contact Wound Dressings Compared with Hydrocolloid Dressings

Six trials with a pooled total of 792 participants investigated the effect of a basic wound contact dressing compared with a hydrocolloid dressing (Holm 1998; Michie 1994; Persson 1995; Shinohara 2008; Wikblad 1995; Wynne 2004). The basic wound contact dressings were predominantly gauze.

Michie, Wikblad y Wynne described results on SSI after clean surgery, but each author on different terms, hence, no pooled data analysis was possible and there is no joint conclusion available; Wynne found no differences between hydrocolloid-dressed 6/267; (2%) and basic wound contact-dressed wounds 6/243; (3%) (RR 0.91; 95% CI 0.30 to 2.78).

The pooled data from the three trials that presented SSI data on contaminated surgery (Holm 1998; Persson 1995; Shinohara 2008) showed no differences between groups with a RR 0.57; 95% CI 0.22 to 1.51.

Basic Wound Contact Dressings Compared with Silver Dressings

Eight trials with a pooled total of 1959 patients, examined differences between these two types of dressings. Two authors included participants undergoing clean surgery (Dickinson Jennings 2015; Politano 2011). Six studies compared the use of a basic wound dressing with a silver-containing dressing in surgery at risk of contamination. Four studies involved

colorectal surgery (Biffi 2012; Kriegar 2011; Prather 2011; Ruiz-Tovar 2015). Bennett randomized 524 participants who had undergone a caesarean section and Ozaki randomized 500 people undergoing a non-emergency surgical procedure for peripheral vascular disease.

After analysing data of the two groups (clean surgery = 2 studies and potentially contaminated surgery = 6 studies) the Cochrane revision on the subject concludes that it is uncertain whether silver dressings increase or reduce SSI for either group with a RR 1.11; 0.47 to 2.62 for clean surgery and RR 0.83; 95% CI 0.51 to 1.37 for the potentially contaminated group.

Basic Wound Contact Dressing Compared with Non-Silver Antimicrobial Dressings

Martin-Trapero randomized 197 participants undergoing elective laparoscopic cholecystectomy to a basic wound contact or a Phenilmetil biguanide (PHMB) impregnated antimicrobial dressing. SSI in the wound contact dressing group was 5% (5/101); while the PHMB dressing-treated group had 1% (1/96). As the 95% CIs are wide and include benefits (in terms of reduced SSI risk) and harms (in terms of increased SSI risks) differences between the two groups remain unclear (RR 0.21, 95% CI 0.03 to 1.77).

Conclusion

Authors of the Cochrane revision conclude that there is insufficient evidence to determine whether covering surgical wounds healing by primary intention, with wound dressings, reduces the risk of surgical site infections (SSIs), or if any particular type of wound dressing reduces the risk of infections more than another. The review also failed to demonstrate any clear advantage of one dressing type over another (or wound exposure) for improved scarring, pain control, patient acceptability or ease of removal.

TOPICAL ANTIBIOTICS

The role of topical antibiotics has not been consistently supported by evidence and, therefore, they are not included in current guidelines for the prevention of SSI. There are thought to be benefits in using antibiotics topically rather than orally, or intravenously, as topical antibiotics act only on the area of the body where they are applied, there is less likelihood of unwanted effects that affect the whole body, such as nausea and diarrhea. Topical antibiotics are also thought to reduce the chances of bacterial resistance.

The most common method of application of topical antibiotics is in the form of an ointment. Other possible delivery methods include cream, lotion, solution, gel, tincture, foam, paste, powder, and impregnated dressings. An ointment base classically contains 80% oil and 20% water, and therefore is more occlusive and will drive the medication into the skin more rapidly than a solution or cream base; thus, ointments are an optimal delivery method for topical antibiotics.

In 2016 the Cochrane Database of Systematic Reviews selected 10 randomized controlled trials, including 6466 patients, assessing the effectiveness of topical antibiotics on preventing

SSI, to determine whether the application of topical antibiotics to surgical wounds that are healing by primary intention reduces the incidence of SSI and the incidence of adverse outcomes (allergic contact dermatitis, infections with patterns of antibiotic resistance and anaphylaxis). All forms of topical antibiotics were included (creams, impregnated dressings, ointments, etc) provided that their application followed wound closure by primary intention. Silver and antiseptic impregnated dressings were excluded given that these substances did not match the definition of antibiotic.

The results of this systematic review are summarized in the following sections as they gather the most recent evidence on the subject.

Topical Antibiotic versus No Topical Antibiotic

The results of eight trials were pooled (5427 participants) using a random-effects model. The -no topical antibiotic- group included: inert ointment (Dire 1995; Dixon 2006; Heal 2009; Smack 1996) and no treatment (Caro 1967; Dixon 2006; Gilmore 1973a; Kamath 2005; Khalighi 2014). There were *fewer SSIs with topical antibiotics than without* (RR 0.61; 95% CI 0.42 to 0.87). There was an absolute risk difference of 20 fewer SSIs per 1000 patients (95% CI 7 fewer to 31 fewer) and a *number needed to treat to benefit* (NNTB) with topical antibiotics to avoid one additional SSI (NNT) of 50. There was moderate inter study heterogeneity ($I^2 = 44\%$). The quality of evidence for this outcome was graded as moderate, downgraded once for the proportion of the information from studies at high risk of selection bias, as this was sufficient to affect the interpretation of the results, a sensitivity analysis was performed to examine the effect of removing the studies at high risk of bias on I^2 and RR (Caro 1967; Dixon 2006; Gilmore 1973). The effect estimate was robust to removal of high risk of bias studies (RR 0.49, 95% CI 0.35 to 0.67; 3026 participants; 5 studies; $I^2 = 0\%$).

No clear difference between groups for risk of allergic contact dermatitis was found (RR 3.94, 95% CI 0.46 to 34.00).

Topical Antibiotic versus Topical Antibiotic

One study (99 participants) was a head-to-head comparison of mupirocin and neomycin (Hood 2004). There was no clear evidence of a difference between mupirocin and neomycin in risk of SSI (RR 0.20; 95% CI 0.01 to 4.14; $P = 0.3$). The quality of evidence for this outcome was rated as very low. Another study was a four-arm trial; two arms of which were antibiotic arms combination ointment (neomycin sulphate, bacitracin zinc, and polymyxin B sulphate) versus bacitracin zinc (Dire 1995). Comparison of the results for these two arms showed no clear evidence of a difference in risk of SSI (RR 0.83; 95% CI 0.26 to 2.63; 219 participants, $P = 0.75$).

These two trials did not compare similar topical antibiotics and so were not pooled. The quality of evidence of this outcome was rated as very low and was downgraded twice for risk of bias and once for imprecision.

There was no information available for the outcomes of allergic contact dermatitis or anaphylaxis for either study.

Topical Antibiotics versus Antiseptic

Five trials that compared topical antibiotics with antiseptics were pooled (1299 participants) to examine effects on risk of SSI. There were fewer SSIs in those treated with topical antibiotics than with antiseptics (RR 0.49, 95% CI 0.30 to 0.80). This difference reflected an absolute difference in risk of 43 fewer cases of SSI per 1000 people treated with topical antibiotics instead of antiseptics (95% CI 17 fewer to 59 fewer per 1000; NNTB of 24). There was minor inter study heterogeneity ($I^2 = 12\%$). The quality of evidence for this outcome was rated as moderate and was downgraded. A sensitivity analysis was performed to examine the effect of removing the studies at high risk of bias on I^2 and RR (Gilmore 1973a; Iselin 1990). The overall effect was robust to removal of the high risk of bias studies (RR 0.39, 95% CI 0.20 to 0.76) and heterogeneity was reduced ($I^2 = 0\%$).

Two trials (541 participants) compared the effects of topical antibiotics and antiseptics on the rates of allergic contact dermatitis. Pooled analysis indicated no clear evidence of a difference (RR 0.97, 95% CI 0.52 to 1.82; $I^2 = 0\%$, $P = 0.92$). One of the two studies was at high risk of bias and the other was at unclear risk of bias. The overall quality of the evidence was rated as very low

Conclusion

Topical antibiotics probably prevent surgical site infection (SSI) whether compared with antiseptic or to no topical antibiotic (moderate quality evidence). The Cochrane review only identified studies involving clean (class 1), clean contaminated (class 2), and contaminated (class 3) surgery, and no conclusions regarding dirty-contaminated (class 4) surgery can be drawn.

In clean surgery, where the baseline infection rate is already low, and the absolute risk reduction in SSI is smaller, the use of topical antibiotics is probably not justified. In classes 2 and 3, the actual reduction in the rate of infection was 4.3% on average when the use of topical antibiotic was compared with antiseptic, and 2% when compared to no treatment, this means it would require 24 patients, on average, to be treated with topical antibiotics instead of antiseptics, and 50 patients to be treated with topical antibiotics, compared to no treatment, in order to prevent one wound infection.

The Cochrane Database review was unable to draw conclusions regarding the effects of topical antibiotics on adverse outcomes, such as allergic contact dermatitis, due to lack of statistical power. It was also unable to draw conclusions regarding the impact of increasing topical antibiotic use on antibiotic resistance.

ANTISEPTICS

The application of antiseptics such as povidone or chlorhexidine at the end of a surgical procedure, after wound closure and prior to the application of any kind of dressing, is widely extended, though it is very hard to find any scientific base to this practice. Regardless of the

background of this conduct, after tissue manipulation, bleeding, etc. it seems only logical to repeat antiseptic procedures if not to reduce SSI, at least to improve wounds appearance.

Antiseptics are chemical agents that reduce the microbial population on the skin. They should gather certain attributes to be consider ideal, such as: kill all bacteria, fungi, viruses, protozoa, tubercle bacilli and spores; be non-toxic; be hypoallergenic; be safe to use in all body regions; not to be absorbed; have residual activity; be safe for repetitive use.

Several antiseptic agents are available for preoperative preparation of skin at the incision site. Most commonly used include iodine as iodine, povidone iodine, cadexomer iodine or povidone; chlorhexidine as polyhexamethylene biguanide or chlorhexidine. Some authors also include silver as an antiseptic or antimicrobial since it does not meet the criteria that defines antibiotics, but it is not used for skin preparation.

Studies that asses the effectivity of antiseptics versus topical antibiotics or dressings impregnated with these substances compared with other types of dressings are detailed in the sections above.

Chapter 284

CLINICAL EXAMINATION, IMAGING AND BASIC SURGICAL TECHNIQUES

Peter Stefanic*, MD, PhD

Department of Vascular Surgery, East Slovak Institute of Cardiovascular Diseases,
Medical Faculty of Safarik University, Kosice, Slovakia

ABSTRACT

Vascular diseases comprise disorders of the arteries, veins and lymphatic system. This chapter provides a comprehensive overview of basic physical examinations in patients with arterial and venous system disorders. As in other parts of the surgery, and in vascular surgery, history and clinical examination play a very important role. Clinical examination in vascular surgery requires an appreciation of the whole patient with a focus on specific findings typical for patients with vascular disease. Adequate analysis of signs and symptoms often requires the multidisciplinary representation of several experts in vascular surgery, angiology, and radiology. A standard examination of a patient with a vascular disease consists of a standard clinical examination, laboratory procedures and imaging. The main imaging studies for vascular surgery are duplex ultrasonography (DUS), CT-angiography, MR-angiography, and digital subtraction angiography (DSA). This chapter also provides a comprehensive overview of basic vascular surgery techniques. Although the first successful arterial reconstructions appeared at the beginning of the 20th century, the active management of arterial diseases had developed since 1950 when new techniques of vascular surgery had been established. Based on this fact, we can claim that vascular surgery is a young surgical field department. The development of imaging in vascular surgery, particularly DSA, has also significantly contributed to the development of new, modern endovascular treatments. Nowadays, well-designed clinical trials have become the “gold standard” for the assessment of new diagnostic methods and treatments.

Keywords: clinical examination, arterial reconstructions, endarterectomy, CT-angiography, MR –angiography, digital subtraction angiography, vascular graft

INTRODUCTION

Vascular diseases comprise disorders of the arteries, veins and lymphatic system [1]. Atherosclerotic-related cardiovascular disease (CVD) is the leading cause of death in all regions of developed countries [2]. An estimated 17.9 million people died from CVDs in 2016, representing 31% of all global deaths. Of these deaths, 85% are due to heart attack and stroke. Over three-quarters of CVD deaths take place in low- and middle-income countries. Out of the 17 million premature deaths (under the age of 70) due to noncommunicable diseases in 2015, 82% are in low- and middle-income countries, and CVDs caused 37% [3]. Peripheral artery disease (PAD) is no exception, so greater focus is required on prevention of the disease in low- and middle-income countries. PAD impairs quality of life and is associated with a significantly increased risk of major cardiovascular events and death; PAD is the essential cause of amputation worldwide [4].

However, during the last twenty years, CVD age-specific death rates fell by greater than 40% in high-income countries, which is also probably related to modern diagnostic methods [5]. As in other parts of surgery, including vascular surgery, patient history, and clinical examination play a very important role. Adequate analysis of signs and symptoms often requires the multidisciplinary representation of several experts in vascular surgery, angiology, and radiology [1]. First, when a patient comes to the hospital, the patient's main complaints should be determined and the physical examination should be correlated with the history and should also provide a bridge to the pathophysiology of the disease process [6]. When the patient's history is known and physical examination is completed, imaging diagnostic studies can be ordered, if necessary, to localize the vascular disease or quantify the extent of the vascular pathological process. The main imaging studies for vascular surgery are DUS, CT-angiography, MR-angiography, DSA and also in some specific situation, single photon emission computed tomography/computed tomography (SPECT/CT) and positron emission tomography (PET)/CT. Determining the correct diagnosis always begins by identifying the signs and symptoms of the patient. It is important to get a chronological description of the

development and progression of the patient's main complaint from the first symptom to the present [7]. After proper diagnosis, another very important thing is an indication of surgical, endovascular, or conservative treatment [8]. Although surgical techniques in vascular surgery have undergone modification for several years, standard surgical techniques are used for the treatment of both arterial and venous diseases. Although the first successful arterial reconstructions appeared at the beginning of the 20th century, the active management of arterial diseases has developed since the 1950s when new techniques of vascular surgery have been established. It should be mentioned here that *Alexis Carrel* was awarded the Nobel Prize in Medicine in 1912 for inventing the modern vascular suture that is still used today.

In 1947, Dos Santos performed the first femoral endarterectomy. Dubost did the first resection of a ruptured aneurysm of abdominal aorta and replacement by allograft in 1952. The first resection of carotid bifurcation for prevention of recurrent cerebral ischemia was carried out by Eastcott in London in 1954. The great development of vascular surgery brought the introduction of prosthetic grafts by Vorhees in 1952. That enabled De Backey to resect abdominal aortic aneurysm and replace it with a synthetic graft in 1955. Seldinger performed the first angiography with a catheter in 1952, and more than twenty years later Gruntzig, in 1974, was the first who did percutaneous transluminal angioplasty and started the modern era of endovascular treatment [9].

CLINICAL EVALUATION

In surgery, including vascular surgery, history and physical examination play a crucial role. It is possible to make a diagnosis and predict the underlying anatomic pathology based on patient history and basic physical examination alone. The anatomy of the vascular disease often correlates with the location of symptoms. The physical examination should progress from inspection to palpation and auscultation. During the inspection, it is necessary to monitor skin changes such as atrophy, edema, cyanosis or mottling, pallor and rubor, tissue loss, and ulceration. All skin changes should be identified, quantified, and fully described. Motor limbs function should also be documented and quantified. During palpation, differences in temperature and sensation should be noted and compared with the contralateral side. All pulses should be evaluated and classified in typical places (carotid artery, brachial artery, radial and ulnar artery, femoral, and popliteal artery, anterior, and posterior tibial artery) [10]. The initial onset of clinical symptoms that may indicate acute or chronic vascular disease, and the location of all symptoms is also essential. Also important are factors which aggravate or relieve symptoms, for example, activity, leg position, temperature, or pressure [7, 8].

History, Signs, and Symptoms in a Patient with Artery Disease

When arterial occlusive disease affects peripheral arteries of the lower extremities, we speak about PAD (peripheral arterial disease). Peripheral artery disease can be acute – acute artery occlusion or chronic – chronic peripheral artery disease with typical symptoms of chronic artery insufficiency. Patients with the PAD most commonly have long-standing

symptoms [11, 12]. Peripheral arterial insufficiency is predominantly a disease of the lower extremities. Pain is syndrome typical for ischemia, which can appear after walking in the form of claudication or it can also be present without physical exercising in the form of rest pain. Both claudication and rest pain are typical symptoms of chronic peripheral artery disease [11]. PAD symptoms can be described as cramping, aching, fatigue, or numbness. Symptoms for PAD are secondary, as a result of decreased circulation, and the relief occurs promptly after the cessation of activity. Claudication is distinguished from other types of pain in the extremities (because of lactic acid accumulation in the muscles) in that it does not occur at rest. Depending on the location of the arterial stenosis or occlusion, the patient may have claudication pain in any of the three major muscle groups of the lower extremity: the buttock - aortoiliac occlusion, thigh femoropopliteal, and tibial occlusion, or calf - tibial occlusion. The triad of intermittent claudication of thigh and buttock muscles, impotence, and diminished or absent femoral pulses are associated with aortoiliac occlusion and is often referred to as Leriche syndrome. PAD symptoms are aggravated if the patient lies down and elevates the extremity. Ischemic pain awakens patients at night [7, 11]. For progressive atherosclerotic obstructive disease, ischemic pain at rest and developing non-healing ulcers or wounds (Figure 1) are typical. Defects are usually very painful. Chronic ischemia produces gradual soft tissue and muscle atrophy. Patients with progressive critical limb ischemiamay very often sleep with their foot continually hanging over the edge of the bed. Small atheroembolic debris arising from atherosclerotic plaque or emboli can occlude small peripheral arteries. Those patients will have a painful bluish discoloration of digits, resulting in “blue toe syndrome.” Involved fingers are felt by patients as cold and numb to touch, and the toes are blue. PAD most commonly occurs in older patients (20% of people older than 65 years) [13]. In younger patients, symptoms like PAD can be associated with popliteal artery obstruction from muscular or tendinous entrapment and aneurysm or mucinous degeneration of the artery [7, 14].

Figure 1. Critical limb ischemia – wet gangrene.

The discomfort of the upper extremity associated with activity can be associated with stenosis or occlusion of the axillary or subclavian arteries. Symptoms are induced by physical activity and relieved by rest [15].

Specific is Thoracic Outlet Syndrome where the subclavian artery (figure 2), vein, or brachial plexus and its trunks are compressed within the scalene triangle. Compression can occur due to muscle abnormality or more often bone abnormalities, such as a cervical rib or anomalous first rib. Chronic compression can develop into thromboembolism, occlusive disease, or an aneurysm. Arterial symptoms are less common and often the result of peripheral emboli. The most common is neural TOS. Patients will complain of arm fatigue, finger numbness, pain, and discomfort when they are working with the arms elevated above the head, or when performing abduction of the arm [16].

Figure 2. DSA, thoracic outlet syndrome, subclavian artery compression with anomalous rib and brachial artery occlusion.

Acute artery occlusion is associated with very intense pain, which occurs very suddenly. Specific clinical symptoms for acute artery occlusion are “6 Ps” pallor, pain, paresthesia, paralysis, pulselessness, and poikilothermia. The other typical clinical manifestation of ischemia is coolness. Loss of sensitivity and further loss of motoric function of muscles and paralysis are the main signs of acute ischemia [17]. In acute artery occlusion, the patient will first notice a change in the skin color, a decrease in sensation, and coolness to the touch [7]. After these signs, motoric dysfunction of extremities starts. Motoric dysfunction is consistent with severe limb-threatening ischemia. Those patients do not have good collateral circulation; therefore, ischemia is sudden and severe. Arterial injuries have similar acute symptoms. Embolism is typical for patients with atrial fibrillation [7, 9, 17].

Symptoms of extracranial carotid artery disease are most often caused by embolization of the internal carotid artery by atrial fibrillation or thrombosis of the artery at the atherosclerotic plaque. Arterial emboli account for approximately one-quarter of ischemic strokes in Europe and North America. 80% of these originate from extracranial carotid atherosclerotic lesions

(Figure 3) [18, 19]. The most common lesion is at the bifurcation of the common carotid artery.

Figure 3. Atherosclerotic plaque from the internal carotid artery.

The neurologic dysfunction associated with microemboli may appear as sudden transient ischemic attacks (TIA), or if the symptoms persist, it is an ischemic stroke – the patient had an ischemic lesion in the brain. An embolus to the ophthalmic artery, the first branch of the internal carotid artery, produces a temporary monocular loss of vision called amaurosis fugax [9, 19]. Acute occlusion of a common or internal carotid artery leads to the sudden onset of neurological symptoms as expressive aphasia, hemiparesis, or hemiplegia contralateral to the occlusion site. Neurological symptoms also depend on collateral brain arteries' function. In the worst case, the occlusion of the internal carotid artery may also lead to coma and death [20].

Pain in the back can be the main symptom of a rupture of abdominal aorta aneurysm (AAA). Patients with AAA are usually asymptomatic until they expand or rupture. Patients may feel back, flank, abdominal, or groin pain for some time before rupture. At times, AAA may cause symptoms from local compression, including early satiety, nausea, vomiting, compression urinary symptoms, or venous thrombosis from venous compression. Other symptoms include abdominal pain, groin pain, embolic phenomena affecting the toes [9, 21, 22]. Very often, patients may describe a pulse in the abdomen and may feel a big pulsatile mass. Quick expanding AAA commonly causes sudden, severe, and constant low back, flank, abdominal, or groin pain. The most typical manifestation of rupture is abdominal or back pain with a pulsatile abdominal mass. The pain usually irradiates into the back and occasionally into the inguinal region. Transient hypotension should prompt consideration of rupture because this finding can progress to frank shock. Unfortunately, the classic triad of pain, a pulsatile abdominal mass, and hypotension are not always present [9, 22].

Peripheral artery aneurysms (Figure 4) are usually asymptomatic but sometimes may manifest themselves with symptoms when there is local compression of other structures such as nerves or veins, with ischemia, or rarely with rupture. Symptoms from recurrent peripheral embolization to the leg are often transient. Thrombosis of the peripheral aneurysm and consequent thrombosis of peripheral arteries is another severe complication of the peripheral aneurysm. Thrombosis of aneurysm leads to acute limb ischemia, and the clinical manifestation is the same as acute ischemia [23].

Figure 4. Peripheral artery aneurysms – brachial artery.

Chronic mesenteric ischemia is also characterized by abdominal pain, which characteristically appears 15-30 minutes after the beginning of a meal and lasts for an hour or longer. Other clinical signs are weight loss, fear of eating, postprandial abdominal discomfort, and epigastric bruit. The early hallmark of acute mesenteric ischemia is severe pain but minimal physical findings. The abdomen remains soft, with little or no tenderness. Later, as bowel necrosis develops, signs of peritonitis appear with marked abdominal tenderness, guarding, rigidity, and no bowel sounds. If bowel ischemia progresses, the stool may be heme-positive. The usual signs of shock develop and are frequently followed by death [24, 25].

Physical Examination in Patients with Arterial Disease

A complete physical examination for patients with suspected arterial disease consists of several steps. Physical examination begins with observation and inspection.

Inspection

The peripheral arterial disease is very often associated with atrophy of the calf muscles, atrophy of the skin – shin appearance, loss of hair over the lower part of the leg. In the initial stages of PAD, pallor is present in the lower extremities. In advanced stages of ischemia, dependent rubor is observed, and the distal part of the leg and the digits may appear reddish. In patients with critical limb ischemia, the foot may appear edematous, and the skin is tense because the patient hangs the foot over the bed (to relieve the pain). Formation of ischemic ulcers can be observed in a patient with critical ischemia. Ischemic ulcers are usually situated on the peripheral parts of extremities, toes, heels, fingertips, and these ulcers are often small and circinate with pale grayish granulation tissue in the base. Ischemic ulcers can progress to tissue gangrene, which can be dry eschar or wet due to purulent (microbial infection) or serous drainage [7, 11, 12].

On the other hand, in patients with acute occlusion of the artery, the extremities appear pale or cyanotic, and the part of extremities under the occlusion are too cold and cool to

touch. Loss of sensitivity and further loss of motoric function of muscles are the main signs of acute ischemia [7, 17].

The signs and symptoms of extracranial carotid artery disease are very diverse. Characteristic of the symptomatic patient with internal carotid artery stenosis is some neurological deficit. The most common can be ipsilateral facial numbness, sensory loss, transient monocular blindness, dysarthria, aphasia, monoparesis, hemiparesis, hemisensoric deficit or vertigo and dizziness [20].

Some aneurysms, e.g., in the popliteal region, may be visible as large pulsating masses [23].

Pulse Examination

Physical examination of the arteries' function begins with the pulse examination – pulse palpation. If possible, the examiner should use the fingertips of the hand and avoid the thumb. Palpation should start lightly and increase in pressure gradually. Pulses can be palpated in the neck, arms, legs, and trunk and always should be palpated and compared bilaterally. We can document that a pulse is absent, decreased, or normal [1, 26].

The carotid pulse may be palpated in the mid-neck region, anterior to the sternocleidomastoid muscles. Especially on the neck, pulse contour can impart information concerning heart function, valvular heart disease, or proximal stenosis [7].

Pulses on upper extremities are examined on brachial, radial and ulnar arteries. The brachial pulse is superficial, and it may be palpated along the inferior border of the biceps muscle. The radial and ulnar pulse are palpated in the wrist. The radial artery is more superficial than ulnar, so the pulsations in the radial artery are usually easy to palpate [1, 10].

On the legs, pulses may be examined at four levels of arteries. The common femoral artery pulse can be palpated in the inguinal area around the inguinal ligament (one-third of the distance from the pubis to the anterior superior iliac spine). The popliteal artery pulse is more difficult to palpate because the muscle obscures the popliteal artery. It may be difficult to palpate in obese or very muscular patients. The patient's leg should be partially flexed and relaxed. The examiner should use both hands to palpate pulse in the popliteal fossa. The examiner's hands encircle and support the knee from each side. On the foot, the posterior tibial pulse can be examined below the medial malleolus. The dorsal pedal artery is localized on the dorsum of the foot between the second and third metatarsal bones. The artery usually lies lateral to the extensor hallucis tendon. In this area, the dorsal pedal artery pulse can be examined [1, 27].

Remember that in patients with PAD, the examiners may have confusion with their own pulse.

During pulse palpation, the size of the artery should be assessed too. Typically, an aneurysm is a pulsatile mass of the palpated artery. Typical localization for aneurysms is the abdominal aorta, popliteal artery, common femoral artery, and subclavian artery. Popliteal aneurysms are commonly bilateral and more frequently associated with AAA. Most aneurysms can be palpated as pulsatile masses, for example, abdominal aorta aneurysm; many patients also feel a big pulsatile mass in the abdomen. Aneurysm of the abdominal aorta can be palpated in thin patients by having them relax their abdominal muscle and then palpating deeply. Pulsatile expansion detected below the umbilicus indicates extension into the iliac

arteries. Most symptomatic iliac aneurysms can be palpated as pulsatile masses on abdominal or rectal examinations. The femoral aneurysm may compress the vein, which causes unilateral edema of the leg [1].

Auscultation

On auscultation of the healthy vessel, nothing is heard. The presence of a bruit is caused by turbulence of blood flow and suggests significant vascular pathology (arterial stenosis, local arterial compression, aneurysmal dilation, or arteriovenous fistula) [27]. If stenosis progresses, the pitch of thrill increases. If stenosis progresses to near occlusion, the intensity of the thrill may decrease. The span of the bruit is also very important because if the bruit continuation into diastole, it points to severe stenosis. Continuous bruits during the systole and diastole are significant for arterio-venous connections [1].

History, Signs, and Symptoms in a Patient with Venous Disease

Clinical signs and symptoms of venous disease are more passive and demonstrate fewer signs than arterial disease. Several acute and chronic diseases of the venous system are manifested by swelling or edema. The etiology of edema may be venous (superficial or deep veins of the lower extremity disease), or nonvenous (disease of the lymphatic system or other systemic illnesses). The disease of the venous system may be acute or chronic and can involve one or both extremities. The clinical history is particularly very important in the evaluation of a patient with the venous disease [1, 28].

The acute venous disease may be presented as superficial vein thrombosis or deep vein thrombosis of the lower extremities and also by thrombophlebitis or varicophlebitis.

Superficial venous thrombosis is associated with inflammation around the vein, erythematous areas overlying a superficial vein. The patient complains of pain along the vein; the affected area is warm, erythematous, and indurated (palpable mass). The symptoms of superficial venous thrombosis are a result of the local inflammation associated with the venous thrombosis. The superficial vein may be distended proximal to the thrombosis [29]. Thrombophlebitis of upper extremities most often involve the cephalic and basilic veins or their branches and is frequently associated with intravenous catheters [30].

Superficial vein thrombosis of the lower extremities is frequently associated with venous varicosities. In the lower extremity, thrombophlebitis typically involves the great saphenous vein and its branches on the medial parts of the leg, but sometimes also small saphenous vein [29, 30].

Deep vein thrombosis (DVT) is the formation of blood clots in the deep veins, predominantly affecting the deep veins of lower extremities (the calf veins, femoral vein, popliteal vein, or exceptionally affecting the deep veins of the pelvis [31]. Deep venous thrombosis is most often associated with a recent patient history of trauma, surgery, travel, using anticonception pills or prolonged immobility [32]. Typical symptoms are swelling, pain, discomfort, pressure, warmth, or fullness in the extremity. Elevation of the affected leg ameliorates the pain, discomfort, and fullness. Deep thrombosis of the distalpopliteal or crural veins is associated with edema of the calf. The left leg is the most frequent site for venous

thrombosis in pregnancy. If the occlusion is in the iliac or proximal femoral part of the vein, the symptoms are presented as edema and cyanosis of the entire extremity. The symptoms are more frequently unilateral, but sometimes if the occlusion is localized in both the iliac vein and also in the inferior cava vein, the swelling is bilateral [31].

The specific type of DVT is phlegmasia. This type of deep vein thrombosis is associated with the vast extent of thrombosis (inferior cava vein, iliac vein, femoral vein). It is very dangerous because the whole leg is edematous, and increased compartment pressure leads to reduced blood flow in the leg. Phlegmasia alba dolens is characterized by swollen, painful, and blanching without cyanosis, while phlegmasia cerulea dolens is characterized by these features in addition to cyanosis, which characteristically progresses from distal to proximal areas and bulla formation [31, 32].

Patients with repeated DVT or thrombophlebitis may have a diagnosis of cancer, and the deep vein thrombosis is a secondary sign of other serious diseases. This is extremely important in the differential diagnosis. Repeated deep vein thrombosis may damage the valves of the vein, and these patients have a chronic problem with swelling of extremities [31].

Chronic venous insufficiency (CVI) typically refers to lower extremity edema, skin trophic changes, and discomfort secondary to venous hypertension. Chronic venous insufficiency can occur after 5 or more years after the first episode of deep venous thrombosis: patients complain about the discomfort, fatigue, itching, cramping, and swelling of the extremity. Long-standing venous hypertension and edema can result in the development of venous stasis ulcers which are usually localized at the medial malleolus. The ulcer is always localized in the skin, changed by hyperpigmentation, lipodermatosclerosis, fibrosis, hyperkeratosis, cellulitis, and atrophy, which are typical changes of chronic venous insufficiency [33].

The most common disease of the lower extremities of the superficial vein is varicose veins. Varicose veins are tortuous and dilated parts of superficial veins caused by hypertension in the vein system together with venous valves insufficiency. Patients complain of leg pain, discomfort, burning, or fullness. Symptoms are reduced by leg elevation. Long-term untreated varicose veins may lead to venous stasis ulcers, skin changes, and rupture with hemorrhage [33, 34].

Deep venous thrombosis on the upper extremities is not as frequent as thrombosis of deep leg veins. Occlusion of subclavian or axillary veins is associated with swelling of the entire arm, localized neck or shoulder pain. Signs of venous congestion such as swelling or edema, pain, cyanosis, and dilation of the superficial veins are among the typical, but not specific symptoms [35]. Thoracic outlet syndrome can be presented as unilateral arm swelling or as deep subclavian vein thrombosis. These symptoms are associated with upper extremity exercise and activity [16]. Subclavian and jugular vein thrombosis is more often associated with hemodialysis vein catheters or central venous catheters [36]. Superficial vein thrombosis and thrombophlebitis of upper extremities are the most commonly associated with indwelling venous catheters [30].

Physical Examination in Patients with Venous Disease

After a detailed history, a thorough physical examination should follow. In the physical assessment of patients with suspected venous system disease, it is, of course, also essential to examine the arterial system. The doctor should begin with inspection, palpation, and then perform noninvasive imaging, ultrasonography, which has a dominant position in examining the venous system. The presence of any swelling, edema, ulcers, skin changes which may be related to venous disease should be noted and described in detail.

Patients with superficial thrombophlebitis have a localized area of erythema and induration. The affected area is painful and warm to the touch, and the involved vein can be felt as a subcutaneous cord. Inflammation most often spreads along the affected vein. Superficial thrombophlebitis may or may not be associated with swelling of the extremity [29].

Diagnosis of deep vein thrombosis is more difficult than superficial thrombophlebitis because clinical findings for superficial thrombophlebitis are sufficient to make the diagnosis. On inspection, the most common clinical findings of deep vein thrombosis usually include unilateral leg swelling under the occlusion of the vein. Patients complain about tenderness, fullness, and pain over the involved vein. On palpation, in thin patients, the cords may be palpated in the inguinal area (common femoral vein) under the inguinal ligament. The affected extremity is more often warmer, and superficial veins are more prominent and visually better (Figure 5). Patients with phlegmasia cerulea dolens have their entire leg massively swollen, full, warm to touch and cyanotic. If compartment pressure increases, the arterial blood flow in the affected limb is reduced when the leg is cold, palid and sensorimotoric deficit can be presented [31, 32, 37].

The main sign for deep vein thrombosis is Homan's sign of calf pain with passive foot dorsiflexion. This examination maneuver should always be performed upon suspicion of deep vein thrombosis. To confirm the correct diagnosis, ultrasonography imaging needs to be performed [31, 37].

Figure 5. Common femoral vein thrombosis – the left leg.

Patients with varicose veins usually complain of leg discomfort, which is described as burning, and the patient may have a feeling of heavy legs. Swelling of the foot and calf may be present and increase during the day [38]. Patients with varicose veins should be examined

in the standing position because the veins are full of blood. On inspection, the varicose veins are presented as dilated, tortuous, superficial veins (Figure 6) [34].

Figure 6. Varicose veins.

Sometimes, inflammation of the varicose vein may be presented (Figure 7). The area affected by inflammation is painful to touch, warm, and erythematous [30, 38].

Figure 7. Varicophlebitis.

Varicosities along the medial side of the leg are generally related to the great saphenous vein or its perforating branches. On the other hand, varicosities along the posterior side and lateral side of the calf are usually associated with the small saphenous vein. The main cause of varicosities formation is incompetence at the saphenofemoral junction or saphenopopliteal

junction, and also may be related to incompetent deep and perforating veins. If the incompetence at the junction is present, the blood flow is reversed and long term high venous blood pressure had dilatated the veins [38]. By palpation, when the patient is in standing position, we detect the range of varicosities which can be a small dilatated tortuous vein, but in some patients, varicosities may be like a cluster of grapes. The great saphenous vein communicates with the deep vein by Hunter, Dodd, Boyd, Cockett, Sherman, and many other vein perforators. The Dodd perforator is located on distal third on the medial side of the thigh. Boyd perforators are located on the proximal third on the medial side of calf under the knee, and the Cockett and Sherman perforators are located at the distal part of the calf and the ankle [39]. Sometimes if perforator insufficiency is present, on palpation, we may find the fascial defects. On palpation, pressure on the insufficient perforator may be painful for the patient. Above the place of an insufficient perforator, we monitor skin changes or bulging. Long-standing superficial venous insufficiency can result in chronic venous stasis changes, (atrophy, hyperpigmentation, fibrosis, and induration) and progression stage can result in venous stasis ulcers (Figure 8) around distal part of the leg and ankle. The venous stasis ulcers are large with irregular borders, moist and erythematous and the skin around may be shiny. The base of the ulcer is usually composed of granulation tissue [33, 34, 38, 39].

Figure 8. Venous ulcer.

Physical examination of patients with varicose veins consists of many tests, for example, Brodie-Trendelenburg test, Perthes test, the cough test, and many others [40].

Distinguishing superficial from deep perforator venous incompetence is possible by using the Brodie-Trendelenburg test. The patient is in the supine position; the leg under investigation is elevated to drain the varicosities. A tourniquet is applied just below the saphenofemoral junction then the patient is asked to stand up. If the tourniquet prevented the filling of the varicosities, the site of reflux is deemed to be the saphenofemoral junction. If a venous refill is less than 30 seconds, it is the evidence of an incompetent deep and perforator system. The Perthes test can help evaluate the cause of deep vein incompetence [40].

The Perthes test is performed in standing position. A tourniquet is applied below the knee, and the patient is asked to do ten heel raises on the spot or walk around. If the varicosities are emptied, the site of reflux is determined to be above the tourniquet. If the varicosities become visible or distended, perforator incompetence and deep vein insufficiency are the cause of the problem. Pain associated with heel raising suggests the possibility of DVT [40, 41].

Saphenofemoral, saphenopopliteal insufficiency, and perforator insufficiency are nowadays usually diagnosed by ultrasonography.

IMAGING

In most cases, the diagnosis of arterial or venous disease can be made based on history and physical examination. Physical examination and testing add a degree of objectivity which can confirm or bring into question the vascular disease. Noninvasive imaging examinations are preferred to diagnostic, monitoring the progression of the disease, or monitoring the results of revascularization procedures.

The main imaging examinations in vascular surgery are duplex ultrasonography (Figure 9), computed tomography (Figure 10), magnetic resonance imaging (Figure 11), and digital subtraction angiography (Figure 12).

Figure 9. Duplex ultrasonography – brachial artery.

Figure 10. CT-angiography.

Figure 11. MR-angiography.

Figure 12. Digital subtraction angiography.

Duplex Ultrasonography

During the last 20 years, progress in DUS has led to its current central role in the diagnostics of vessel disease. DUS is the best diagnostic; perioperative and postoperative screening imaging examination for the evaluation of arterial and venous disease. It is a non-invasive imaging method and for its full availability is considered to be the first line one. The advantage of the DUS examination is its high specificity, sensitivity, non-invasiveness, high availability, low cost, the possibility of endless repetition in monitoring the dynamics of the atherosclerotic process and also the absence of radiation [42, 43].

DUS in-vessel system is performed by a linear multi-frequency probe with a frequency range of 5-10 MHz. The probe generates and then also receives the reflected ultrasound wave, thereby generating an echo that is the source of information in the DUS examination. The instrument analyzes the intensity and frequency shift of the reflected wave from the interface of two physically different media. Essentially, it is a mechanical wave with a frequency of 2 to 15 MHz, which spreads in tissue at different speeds depending on the type of medium – tissue [43]. It is better to use a convex probe in some special situations, for example, to evaluate abdominal vessel or iliac arteries and veins.

DUS combines the evaluation of blood flow (pulsed Doppler spectral analysis) and anatomic information (B-mode and color Doppler imaging). We can get a morphological image of arteries and veins in B mode, and it is a simple evaluation of aneurysm or pseudoaneurysm. Also, in B mode, it is possible to evaluate the morphology of the atherosclerotic plaque in the cross-section. In cross-section, we can measure the width, assess the echogenicity, homogeneity, and surface of the atherosclerotic plaque [43, 44]. Based on echogenicity, this examination makes it possible to distinguish an acute embolic arterial closure from a chronic arterial closure. Using the Doppler effect, we can obtain information about arterial and venous blood flow.

Velocities are detected as frequency shifts in reflected ultrasound from the flowing red blood cells. The arterial narrowing causes an increase in speed at the site of the stenosis and dampening of the velocity waveform beyond [9, 45]. Based on this principle, we can use the Doppler spectral curve to show the blood flow in individual vessels, determine the flow rate, the flow pattern (laminar flow, turbulent flow), which in practice means that we can assess the presence of artery stenosis and determine its size. Doppler can distinguish between a normal, reduced, or abnormal flow [43]. Typical Doppler waveform in peripheral arteries has a triphasic quality. The presence of a triphasic signal nearly always rules out clinically significant stenosis or obstruction. Critical stenosis in blood flow causes dampening of the waveform, which becomes blunted –monophasic. Monophasic Doppler signals that result from the arterial occlusive disease may be difficult to distinguish from venous signals [45]. DUS is a sensitive and specific tool for the assessment of most venous disorders. Ultrasonography is usually used to detect acute deep venous thrombosis and venous reflux and also to evaluate chronic venous obstruction. The linear array transducer 4- to 7-MHz is best for assessing most veins, which are normally 1 to 3 cm below the skin [43, 45].

Deep veins, in the abdomen or pelvis, are better assessed by using lower frequency curvilinear transducers for deeper penetration. Low blood flow settings are most often used. During the vein ultrasonography, four components should be examined: visualization, compressibility, flow, and augmentation [46]. In real time imaging, we can control vein valves. Valsalva's maneuver closes the vein valves, the blood flow stops, and the subfascial

veins expand. If the vein valves are insufficient, the blood flow is reversed. Healthy veins have a thin wall and a different shape. The probe easily compresses healthy veins. In thrombosis, the vein flow stops, and the lumen of the vein is incompressible. Fresh thrombus is hypoechogenic, and the venous lumen is extensively broadened [43]. Part of the ultrasound examination in varicose is the assessment of the saphenofemoral and saphenopopliteal sufficiency. The reflux time in saphenofemoral and saphenopopliteal is assessed in the Valsalva maneuver, eventually proximal compression. The pathological is considered to be above 1 second. In addition to the assessment of the saphenofemoral or saphenopopliteal junction, we also investigate the width of the GSV and SSV. We try to identify the proximal and distal reflux point according to the extent and location of the varicose veins. Duplex sonography is also the method of choice in assessing the size and sufficiency of perforators. Perforator with the confirmed directional flow with reflux time above 0.5 seconds is considered insufficient with dilatation above 4 mm [47].

Computed Tomography

Conventional arteriography, nowadays, is no longer considered the standard imaging modality for vascular disease, because arteriography is an invasive imaging method. At present, CT angiography is the most widely used to diagnose vascular conditions since it is a minimally invasive examination [48].

CT angiography uses a narrow beam of X-rays, intravenous contrast and high-powered computers to generate images of bones, soft-tissues, and vessels in the body. Because there is no need to thread a catheter through the body, a CT-angiography is usually faster and causes less discomfort than traditional angiography. Optimal visualization of the vessels by CT-angiography was not possible until the availability of helical CT. The main advantage of this CT type is the ability of imaging a larger part of the body in a shorter time. This rapid scanning enables visualization of the vessels during the short period when a bolus of contrast medium passes the imaged volume. In this examination, 50-130ml of intravenous contrast is applied for the best visualization of the vessels. The timing of the initiation of image acquisition relative to the injection of the contrast medium is very important for maximizing visualization of vessels in the scanned volume [48, 49].

CT- angiography is not very precise in the quantification of strongly calcified lesions. CT- angiography is a crucial imaging method for the diagnosis of aneurysms and planning of their treatment and is also often used for diagnosis of mesenteric artery stenosis and aneurysms. CT is an excellent modality to evaluate venous pathologies, for example, mesenteric venous thrombosis. The advantage of CT- angiography over other imaging methods is its excellent availability, quick performance, price, and minimum invasivity [9, 48].

CT angiograms are usually performed for the following reasons [48, 50]:

- To detect aneurysms
- To determine whether any blood vessels are torn
- To examine the atherosclerotic plaque composition
- To assess the degree of artery stenosis

- To investigate vascular problems in the brain, such as stroke or cerebral bleeding
- To examine any malformations of the blood vessels
- To control the effectiveness of an earlier endovascular treatment
- To evaluate the results of a bypass surgery
- Angiograms are usually used by surgeons to plan open or endovascular surgery.

The main disadvantage of CT-angiography is the radiation for the patient and the nephrotoxicity of the contrast. Side effects of radiation play an essential role in the clinical decision of whether to order a CT scan, particularly in children. Another disadvantage is the use of nephrotoxic contrast in patients with kidney disease. Large doses of contrast agent used in CT angiography increased the incidence of contrast nephropathy, which is the third most common cause of iatrogenic acute renal failure [49].

Magnetic Resonance Imaging

MRI uses a powerful magnetic field, radio frequency pulses, and a computer to produce detailed pictures of organs, soft tissues, vessels, bone, and virtually all other internal body structures. MRI demonstrates a superior ability to investigate the anatomic and perfusion characteristic of various tissues and organs without radiation injury (not use ionizing radiation) or invasiveness, MRI is usually performed in the detection, diagnosis, staging, grading, and treatment of various diseases [51].

MR-angiography is similar to CT-angiography and uses paramagnetic contrast medium that is applied intravenously. The contrast material most commonly used for an MRI exam contains a metal called gadolinium. Contrast medium is not based on iodine and can be used in case of iodine allergies and in patients with renal insufficiency, which is a significant advantage compared with CT-angiography. The advantage of MRI and MR-angiography over CT/CT-angiography is better soft tissue visualization and better quantification of calcified lesions. High-resolution “bright blood” and “black blood” sequential MRI analysis is capable of the accurate analysis of the ingredients in atherosclerotic plaques and the evaluation of the severity of carotid artery stenosis [51, 52].

MR-angiography is used to [52]:

- identify abnormalities, such as aneurysms, arteriovenous malformation, congenital abnormalities
- detect atherosclerotic plaque and their composition
- detect renovascular disease or visualize blood flow to help prepare for a kidney transplant
- detect injury to arteries
- evaluate arteries feeding a tumor before surgery
- identify dissection of arteries
- detect pulmonary embolism
- evaluate the obstructions of vessels.

Disadvantages of MRI/ MR-angiography are worse availability and higher price compared to CT/CT-angiography. Moreover, CT/CT-angiography is a quicker imaging examination than MRI/MR-angiography. Noteworthy is also the fact that MRI/MR-angiography cannot be used by patients with pacemakers, metallic implants (vessel clips, coils). The procedure time may be shorter than a traditional angiography and requires no recovery period [9].

Digital Subtraction Angiography

The quality of DUS, MR-angiography, and CT-angiography has improved during the past ten years, and in many clinical cases, DUS, MR-angiography or CT-angiography became the preferred choice for the planning of either endovascular or surgical procedures. Angiography is used if we intend to treat patient endovascular or if the information obtained by ultrasound, CT-angiography eventually from MR-angiography is not sufficient for the planning of surgical treatment. Angiographic imaging works on the principle of visualization of vessels filled with contrast medium at the time of radiographic exposure [8, 9, 53]. Contrast medium is applied directly to the arterial system, usually via a catheter (4 – 5 F/1.2-1.5mm) in the right common femoral artery or brachial/radial artery. Patients with stenosis or occlusions in the aortoiliac region have angiography performed through the radial or brachial artery. Contrast medium is usually composed of molecules containing iodine. Contrast medium can be applied to the artery by power injector or manually [8]. The advantage of angiography is that it most precisely identifies the anatomy of arterial occlusive disease and also that endovascular treatment is immediately possible during the diagnostic process. Angiography was very often crucial for planning of infrainguinal arterial reconstructions and also for imaging of arteries of upper extremities and imaging of vessels of hemodialysis access. The disadvantage is using of iodine contrast medium, which can lead to an allergic reaction or can worsen renal functions. Rarely, impaired kidney function or kidney failure can occur following a DSA, especially if you already suffer from kidney disease. Also rarely, severe allergic reactions can occur, especially among people who have had previous allergic reactions to the contrast dye. The other disadvantage is arterial invasivity, which can lead to bleeding. Acute pain, numbness or coolness in arm or leg may signify blockage of the artery. That's why angiography is not used as a first line imaging method nowadays [8, 53].

BASIC SURGICAL METHODS

Surgical treatment of vascular diseases generally consists of basic vascular surgical procedures used to treat arterial as well as venous lesions.

Arterial Incision

Whenever we open the vessel, the vessel should be secured with clamps. We open the vessel with a knife which should cut the vessel directly perpendicular to the lumen of the

vessel so that the incision in the vessel is straight. When we open the vessel with a knife, the microscissors can be used to enlarge the incision. We make oblique or perpendicular incisions on the vessel if we only plan to perform an embolectomy with a Fogarty catheter and not a big reconstruction. Oblique or perpendicular incision prevents stenosis at the site of vascular opening [54].

Closure of the Arterial Incision

We are currently using monofilament polypropylene non-absorbable atraumatic fiber for the suture. It is a very thin fiber and therefore needs to be tied at least six times. The suture is always placed from within outward at each end of the arteriotomy and then tied. One arm of the suture is then run to the center of the vessel incision. The suture at the other end of the arteriotomy is also run to the center, where it is tied to the first suture. This is a simple running stitch (Figure 13) [8, 54, 55].

Figure 13. Simple running stitch – an end to side anastomosis.

Figure 14. Arteriotomy closed by synthetic patch.

If the vessel is narrow and there is a risk of stenosis, it is necessary to close the vessel with the patch, which can be synthetic (prosthetic) or autologous (great saphenous vein). The synthetic or autologous patch is usually used if the artery is less than 5 mm in diameter, in case of presence of significant atherosclerotic plaque at an arteriotomy site, a jagged arteriotomy, or a very tortuous artery. The closure of the vessel by the patch is referred to as a surgery angioplasty. The patch is sutured to the edges of the arteriotomy by one or two running stitches (Figure 14). Surgery angioplasty should not widen the vessel because it would lead to aneurysmal dilatation. However, it should prevent stenosis from exiting the direct vessel suture. In children; it is appropriate to use individual simple stitches concerning the growth of the organism [8, 54, 55].

Embolectomy

Embolectomy is considered to be one of the most common vascular operations, although the number of endovascularly treated patients with acute arterial occlusion has recently increased.

This procedure consists of a transverse or oblique incision on the artery that is closest to it. Subsequently, through the incision, we introduce the Fogarty catheter into the artery centrally to the point above the occlusion, inflate the balloon with water and slowly withdraw the catheter to feel light resistance, suggesting that the balloon touches the artery wall. When the catheter is withdrawn from the artery, the embolus is pushed out through the incision (Figure 15). If we have done the embolectomy properly, there is a quality pulsing inflow. Subsequently, we place the clamp centrally on the artery and through the incision by Fogarty catheter pass into the periphery, inflate the balloon and then pull out the embolus, then rinse the artery with a heparin solution. If we have been successful enough, there is a good backflow from the artery. Angiographic control of artery patency can be performed immediately through the incision. We close the arteriotomy with a tight continuing or single stitch [8, 55].

Figure 15. Embolectomy by Fogarty catheter.

Endarterectomy

Endarterectomy is also one of the most frequent operations of vascular surgery. If the artery diameter is more than half a centimeter, and the atherosclerotic disease process is localized, an endarterectomy is very attractive.

This procedure involves the removal of atherosclerotic plaques that compromise the blood flow (Figure 16). The tunica intima and half part of tunica media of vessel wall are removed, leaving behind the outer part of the media and the adventitia. It can be performed as the sole therapeutic procedure (carotid endarterectomy) or in combination with bypass or endovascular intervention. It should not be performed in an aneurysmal artery because the remaining adventitial layer is too weak and degenerated to withstand arterial pressure. The artery is opened longitudinally, and the plaque is separated from the artery wall in the direction of the arteriotomy and removed. The arteriotomy can be closed primarily or with a synthetic or venous patch. The proximal ending of endarterectomy sharply with scissors without leaving a significant protruding edge. The distal endpoint of the endarterectomy should be flat with a smooth transition from the endarterectomized to the nonendarterectomized part of the surface. Sometimes the atherosclerotic plaque may extend further distally, with no visible end in the open part of the artery, then transaction of the atherosclerotic plaque is necessary, which results in a shelf between the endarterectomized and nonendarterectomized part. In such a situation, suture of the intima and plaque to the adventitia is needed to avoid plaque lifting or dissection by blood flow upon reperfusion. One end of the suture is placed in the atherosclerotic plaque near distal endpoint, and the other suture is placed at the junction of the endarterectomy. The surface area should always be without debris. If the artery is wide enough, close the arteriotomy with a tight continuing stitch, but if the artery is narrow and there is a risk of stenosis, it is necessary to close with the patch [55].

Figure 16. Carotid endarterectomy.

Bypass

This vascular procedure is standard to manage the occlusive disease or to replace dilated or injured vessels. The bypass is usually the most frequent operation of vascular surgery. Sometimes a combination of endarterectomy and bypass is needed to treat, for example, PAD. With the help of a natural (GSV) (Figure 17) or synthetic graft (Dacron, PTFE - polytetrafluorethylene), a surgical bypass routes blood flow around the area of blockage. When a good GSV or sufficient length is not available for bypass, surgeons may choose to use other veins from the arm or leg or to use an artificial synthetic graft. However, there is a fall-off in results for these alternatives. Synthetic grafts are usually used to bypass larger arteries or extra anatomical bypass, but below the groin, the smaller femoral and popliteal vessels are often best bypasses using the patient's own GSV. The surgery does not cure the disease or remove the blockage [8, 55].

Figure 17. Great saphenous vein for bypass.

Usually, the bypass is situated in the anatomical pathways of the affected artery. The graft will sometimes lie deep within the leg, and sometimes just beneath the skin. The precise name given to the procedure depends on where the bypass starts and where it finishes (aorto-femoral, iliofemoral, femoropopliteal, femorotibial, and popliteal-pedal bypass). The most common type of bypass is femoropopliteal (Figure 18), which is used to treat superficial femoral artery occlusion. It possibly uses a natural (GSV) or synthetic graft to create the detour around the blockage beginning at your groin/thigh crease and ending at the inner knee (proximal femoropopliteal bypass), or sometimes the calf (distal femoropopliteal bypass). The graft is sewn to the artery at both ends with fine stitches. For an aortic bypass, a synthetic graft made of fabric (Dacron) or plastic (PTFE, Gortex) is used.

Sometimes extra-anatomical bypass grafting is needed, which is a recognized method of re-vascularisation [8, 54, 55].

The term extra-anatomic bypass applies to any bypass graft that is placed in a site different from that of the native arterial segment being bypassed [56, 57]. The most common examples of the extra-anatomic bypass in the past and also today are axillofemoral and femorofemoral crossover bypass and their combination [58]. Less common and more complex bypasses include obturator, thoracofemoral, and supraceliac-to-iliofemoral bypasses.

Extra-anatomical bypasses offer a treatment strategy for patients in whom the risks of conventional anatomic bypasses make their use prohibitive. Nowadays, they are usually used in situations where there is an active graft infection (including mycotic aortic aneurysms, infected aortic prostheses, aortoenteric fistulae, infected femoral artery aneurysm, prosthetic graft groin infection), multiple abdominal operations that result in adhesions, history of radiation, or to avoid performing surgery in previously operated anatomical planes [59, 60].

Figure 18. Femoropopliteal venous bypass – (A) distal anastomosis and (B) proximal anastomosis.

Bypass surgery carries significant risks, including cardiovascular complications, blood clots, infections, and even death. The most serious complication is the infection of synthetic graft that is very difficult to treat. Overall, bypass surgery is immediately successful in 90 to 95% of cases. The lifespan of a surgical bypass depends on the health of the arteries, the type of graft used (GSV grafts last longer than synthetic), other comorbidities, such as diabetes, kidney failure and also lifestyle (smoking). The short and long-term success of the procedure is most closely linked to two main factors. The first is the material employed for the bypass graft itself, and the second is the quality of arteries in the lower leg to which the graft is attached [8, 61].

Careful assessment of the risks and benefits before surgery, as well as a diligent medical, anesthetic, and surgical care, ensure the best outcomes following bypass operations.

TYPE OF GRAFTS

Surgical bypass is very often used in the treatment of arterial and venous disorders (occlusions, aneurysms, arterial, and vein injuries). The success of surgical bypass is directly dependent on the conduit used, which can be biologic or synthetic. The ideal vascular graft should be durable, resistant to thrombosis and infection, readily available, and cheap. It is best for the graft to have similar properties to the vessel part to be replaced. In vascular surgery, we use two main types of vascular grafts (biological and synthetic grafts). Although the perfect vascular graft does not exist, the autogenous vascular graft is closest to the ideal graft [62].

1. Biological Grafts

- A) Autologous - Venous autologous graft
 - Arterial autologous graft
- B) Allogeneous
- C) Xenografts

Autologous vascular grafts are taken from the patient. As an autologous material in vascular surgery, an artery or a vein can be used. The most common used venous autologous graft is GSV. Other veins, as the SSV or cephalic vein from the arm, are rarely used. The great saphenous vein is the preferred conduit for bypass because long lengths of vein can be harvested, removal is inconsequential, and the vein removal procedure is effortless. Advantages of the autologous vein are excellent patency, venous graft needs flow only 50ml/min not to thrombose, and superior resistance to infection. The disadvantages of the venous grafts are that they are of small diameter and may be used only for peripheral artery bypasses and not for aortic and iliac artery replacement. The other problem of autologous venous grafts is the limited amount of appropriate autologous grafts in one individual. The great saphenous vein is commonly used for the bypass of the lower and upper extremity artery and also for carotid, coronary, and visceral artery. On the other hand, GSV has also been preferentially used in the reconstruction of arteriovenous fistulae needed for hemodialysis [8, 62, 63].

Autologous arterial grafts are used less frequently than venous grafts in vascular surgery. Arterial grafts (internal mammary artery) are standardly used in cardiac surgery for aortocoronary bypass. The desobliterated segment of occluded superficial femoral artery can be used as an arterial graft, in a situation when appropriate GSV or SSV graft is not available, especially in patients with prosthetic graft infection [62, 63].

Allogeneous grafts (allografts) are arteries or veins that are transplanted from one individual to another within the same species. Allografts in vascular surgery have been used mostly in three distinct clinical settings: bypass in the absence of suitable autogenous graft, arteriovenous access reconstruction, and replacement of infected prosthetic grafts. When the autogenous GSV is not available, alternative allogeneous GSV conduit can be used for lower extremity revascularization. Also, for arteriovenous access reconstruction, a donor vein can be used, if the autogenous conduit is not suitable. One of the treatment options for infected aortic prostheses is reconstruction with aortic allograft. The allogeneous grafts tend to form aneurysms and rupture or produce stenoses. This is due to the degeneration of the allogeneous grafts by immunological mechanisms. The patency of bypasses with allogeneous grafts are worse compared to the patency of autologous or prosthetic grafts [8, 62, 64].

A special type of vascular grafts is xenograft. Xenografts are vessels transplanted from an individual of non-human species to an individual of human species. The most often use of xenograft are those from the bovine pericardium. The main indication for the usage of xenografts is the treatment of prosthetic infections. They are better used as allogeneous grafts and have comparable patency [64].

2. Prosthetic Grafts

Although the functions of autogenous vascular grafts (arterial and vein) are many, there exist multiple clinical situations in which these grafts are inadequate. These unmet demands led to the development of prosthetic grafts. Various materials have been tried for the manufacture of the vascular graft. Standard materials used for the production of prosthetic vascular grafts are polyethylene terephthalate (Dacron) and polytetrafluoroethylene (PTFE). These grafts are used with excellent success for the bypass of large vessels, an aortoiliac region mainly (Dacron), and also for infrainguinal revascularization (PTFE, Dacron). Armored vascular grafts are commonly used for extra-anatomic bypasses. Synthetic grafts offer almost endless availability and a wide variety of sizes. In general, synthetic grafts cannot be used in infected areas, because the risk of infection, structural deformation, and also occlusion is very high. The disadvantage of synthetic grafts is that they are prone to thrombose more often, compared to the autologous grafts because prosthetic grafts need a higher flow of 150 ml/min not to thrombose. Prosthetic grafts patency rates are acceptable for aorto-iliac reconstruction because of high flow in aortic and iliac circulation and low outflow resistance. On the other hand, infrainguinal reconstruction is associated with low graft patency because of high outflow resistance. In the pediatric population, the inability of synthetic prostheses to match the growth of the child is an additional limitation for use [8, 65].

CONCLUSION

Clinical examination in vascular surgery requires an assessment of the whole patient with a focus on specific findings typical for patients with vascular disease. Adequate analysis of signs and symptoms often requires the multidisciplinary representation of several experts in vascular surgery, angiology, and radiology.

The main imaging studies for vascular surgery are duplex ultrasonography, CT-angiography, MR-angiography, and digital subtraction angiography. Knowledge of basic imaging is essential for proper diagnosis and a subsequent indication of either surgical or endovascular treatment of vascular diseases.

The chapter also provided a comprehensive overview of basic vascular surgery techniques which represent necessary knowledge of every vascular surgeon. Despite the massive development of endovascular treatment, knowledge of vascular surgical treatments is essential, very often finding that surgical treatment is the only possible healing method for rescuing not just extremity but also life. Nowadays, well-designed clinical trials have become the “gold standard” for the assessment of new diagnostic methods and treatments.

Chapter 285

AORTIC ARCH AND SUPRAAORTIC BRANCHES

František Sabol*, MD, PhD

Department of Heart Surgery of East Slovak Institute of Cardiovascular Diseases,
Pavol Jozef Safarik University, Kosice, Slovakia

ABSTRACT

The introduction of the chapter focuses on embryology and anatomy of the aortic arch, which directly follows the text focused on congenital developmental aortic defects, their manifestation and surgery. Furthermore, attention is drawn to the most feared diagnoses of aneurysm and aortic arc dissection. The description of surgical interventions in this anatomical site includes both the standard purely surgical procedures and the currently preferred hybrid approaches. The chapter also includes summarizing of forms of brain protection during surgical intervention. The author thus tried to give a comprehensive surgical view of the discussed issue.

Keywords: aortic arch, cerebral protection strategies, aortic arch aneurysm, aortic dissection

EMBRYOLOGY, ANATOMY AND PHYSIOLOGY OF THE AORTIC ARCH

The development of the aorta begins in the third week of fetal development. It is a complex and complicated process that can lead to a number of physiological variations and also pathological malformations. The primitive aorta consists of two anterior and two posterior branches. The anterior branches then form the aortic sac and the posterior branches the tissue for the descending aorta. There are six arches between the anterior and the posterior aortic structures. The definitive anatomy of the aorta and its basic branches is due to the regression of some parts of these primitive structures, while others form definitive structures. In principle, the first arch creates the arteria maxillaris, the second arch the arteria stapedia and the arteria hyoidea. The third arches then form the arteria carotis communis. The fourth left arch creates the final arch of the aorta. A part of the primitive anterior right aorta further creates the truncus brachiocephalicus [1]. The fifth arches regress rapidly and often are not

* Corresponding Author's Email: fsabol@vussh.sk

even present and finally the sixth arches form the pulmonary arteries [2]. On the dorsal aorta then starts the seventh intersegmental artery as a prerequisite for the formation of an arteria subclavia bilaterally (Figure 1) [1].

Figure 1. Aortic development (1st – 6th - 1st – 6th pharyngeal branch; AA – aortic arch; DA – ductus arteriosus; LCCA – left common carotid artery; LSA – left subclavian artery; PA – pulmonary artery; RCCA – right common carotid artery; RSA – right subclavian artery).

Thus, the normal left-sided aortic arch originates from the fourth left-sided primitive aortic arch. Truncus brachiocephalicus originates from right-sided anterior primitive aorta. Thus, by regression of the posterior right primitive aorta distal to the seventh intersegmental artery, a part of the definitive right artery subclavia is formed. It finally embryologically consists in the proximal-distal direction of the fourth right aortic arch, part of the right dorsal aorta, and the right seventh intersegmental artery. The fifth arch bilaterally and the sixth aortic arch on the right physiologically disappear. From the left-sided fourth arch as the base for the aortic arch remains a separate of both the aorta carotis communis and the left subclavian artery. This branching is present in 70% to 80% of the healthy population. The most frequent variation is the common separation of the left-sided arteria carotis communis with the right-sided arteria carotis communis. This type of the arch can be also found in cats. Further the common division of arteria carotis communis sinistra from arteria brachiocephalica dextra is present at 9 to 13% of population. In 5 to 6% of patients, we find a separate division of the arteria vertebralis sinistra arteria from the aorta, proximal to the left-sided arteria subclavia [1].

Arcus aortae is a continuation of the ascending aorta. It begins slightly to the right of the medial plane behind the second sternocostal joint. The arch runs first to the left diagonally back to the left side of the front wall of the trachea. Subsequently, it crosses the trachea from the left and continues caudally to the body of the fourth thoracic vertebra where it passes into the descending thoracic aorta. There is a slight narrowing, aortic isthmus, at the interface of the aortic arch and its descending part behind the sinister subclavian artery. It is located in the prenatal ductus arteriosus site. Thus, the entire arch of the aorta lies in the mediastinum superius, surrounds the left bronchus and reaches the height of the centre of the manubrium sterni which means about 2.5 cm below the jugular fossa. The aortic arch shadow is also

visible in the anterior-posterior image of the chest. At the beginning it reaches a width of 28mm, at the end 20mm. To the left of the aortic arch lies the left pleural cavity. On the left edge the aortic arch crosses the phrenicus nerve and the vagus nerve that produces the laryngeus recurrens nerve. That surrounds the ligamentum arteriosum and returns cranially on the right side of the aortic arch. The trachea, the plexus cardiacus profundus, the nervus laryngeus recurrens dexter, the oesophagus, the ductus thoracicus, and the vertebral bodies [3, 4] are then on the right and behind the aortic arch.

From the arch separate the truncus brachiocephalicus, arteria carotis communis sinistra and arteria subclavia sinistra, which are crossed from the front by vena brachiocephalica sinistra. The separation of the first of the branches varies from the beginning of the arch to the highest point of the arch. More rarely, the left-sided branches may separate together as the left-sided truncus brachiocephalicus. However, we can also find an individual separation of arteria carotis interna and arteria carotis externa directly from the aortic arch. The right arteria subclavia normally separates from the truncus brachiocephalicus beyond the upper edge of the sternoclavicular articulation. Initially, it heads slightly cranially behind the clavicle, subsequently behind the musculus scalenus anterior, over the right rib into the axilla where it turns into the arteria axillaris. The left arteria subclavia separates from aortic arch mostly individually, then it also extends beyond the musculus scalenus anterior [3, 4].

Compared to the ascending or the descending aorta, the pressure load of the aortic arch is loaded with increased pulse tension as well as increased blood flow [5]. Pulsatile stress loads the aortic arch in both the longitudinal and the circumferential directions. Due to the elongation of the aortic arch described in the older population, we can assume a higher pulsatile stress in the longitudinal direction of the aortic arch. In supraaortic branches, the pulsatile stress is considerably limited. This stress affects both the development of aortic arch diseases and the long-term stability of implanted stentgrafts [5].

Figure 2. Ishimaru classification of the aortic arch landing zones (AR – aortic root; Z0 – ascending aorta up to the truncus brachiocephalicus; Z1 – part of the aortic arch between truncus brachiocephalicus and arteria carotis communis l.sin; Z2 – part of the aortic arch between arteria carotis communis l.sin and arteria subclavia l.sin; Z3 – proximal descending thoracic aorta distal to the arteria subclavia l.sin; Z4 – midportion of the thoracic descending aorta) – free according to [5].

In terms of interventional endovascular medicine, we divide the thoracic aorta according to Ishimaru classification into landing zones. Landing zones represent parts of the aorta unequivocally characterized by the possibility of stentgraft anchoring at the site. The portion of the aorta from the sinotubular junction to the distal edge of the truncus brachiocephalicus is Z0. The Z1 zone is linked to Z0 and ends at the distal edge of separation of the left arteria carotis communis. The continuation is zone Z2 ending at the distal edge of the left arteria subclavia. Another zone is zone Z3, which represents the proximal part of the thoracic descending aorta (Figure 2). Another part of the thoracic aorta is called zone Z4, which is further subdivided into subdivisions marked with letter T and a number correlating to the number of the thoracic vertebra at that height. The most proximal part of the Z4 zone due to the proximity of the fourth thoracic vertebra in this topographic location is represented by the T4 segment [5].

CONGENITAL MALFORMATIONS

The incidence of congenital anomalies in the aortic arch in the literature varies from 0.5% to 3% [6]. These variations are due to a defect in embryogenesis and are closely related also to the development of the descending aorta. The diagnoses as anomalous separation of the right arteria subclavia, the presence of Kommerel diverticulum and the coarctation of the aorta, despite the close association with the aortic arch, will be discussed in the chapter on the descending aorta. In the following text we will deal with malformations directly affecting the aortic arch, namely the double aortic arch, the right aortic arch, the persistent fifth aortic arch and the interrupted aortic arch [1].

Double Aortic Arch

The double aortic arch is formed by the persistence of both the right and the left fourth primitive aortic arches, while each side produces ipsilaterally both the arteria carotis communis and the arteria subclavia. This anomaly is most often manifested as a vascular ring when the surrounding of the trachea and the esophagus causes their suppression and consequently dyspnea and/or dysphagia. It is already manifested in early childhood, usually as dyspnea, wheezing and stridor accentuated with the baby's cry. The right-hand side is usually more developed with a larger diameter, in some cases the left-hand side is also atrophied, occurring only as a fibrotic band, where we can also define the condition as a right-sided aortic arch. The preserved fibrotic band, in contrast to the isolated right-hand arch, leads to the above-mentioned manifestation caused by the vascular ring already in early childhood [1]. In vascular ring symptomatology, whether in complete double arch or right-hand arch and fibrotic left side, ligation and transection of one side is indicated depending upon side dominance (Figure 3) [1].

Figure 3. Embryogenesis of the aortic arch and congenital anomalies (pointers show localization of the aortic arch regression and attributed congenital anomalies; LCCA – left common carotid artery; LSA – left subclavian artery; RCCA – right common carotid artery; RSA – right subclavian artery).

Right Aortic ARCH

The right aortic arch is created by preserving the right-hand fourth primitive aortic arch and more, or less, by the atresia of the left-sided fourth arch. There are several anatomical variants of this diagnosis depending on the site of involution of the left-sided part (Figure 3).

The right aortic arch with the aberrant left arteria subclavia and retroesophageal diverticulum is the most common modality of this diagnosis [7]. The pathology is due to the regression of the left fourth primitive aortic arch at a level between the separation of the arteria carotis communis and the arteria subclavia. A portion of the left dorsal aorta often persists, thus forming a retro-esophageal diverticulum, from which subsequently separates the left arteria subclavia. This nozological unit, after double aortic arch, is the second most common malformation causing a vascular ring with symptomatology of esophageal and respiratory depression in early childhood. Further, it can be supplemented by persistent left-sided ductus arteriosus or ligamentum arteriosum located between pulmonary artery and retro-esophageal recess [1, 8].

The second modality of the right-sided aortic arch is the presence of an aberrant left arteria subclavia without retroesophageal diverticulum. It arises from the involution of the left fourth and sixth primitive aortic arch, whereby the left posterior aorta does not participate in the definitive descending aorta. An important fact is the absence of the left-sided ductus arteriosus, thus severely disrupting the vascular ring. Thus, possible coarctation of the aorta may occur on the right arch in the usual height correlating with the leftward variant. The diagnosis may itself be asymptomatic but is often associated with other cardiac anomalies such as Fallot's tetralogy, less often coarctation of the aorta [1, 9].

In the right-sided aortic arch can be preserved also the left-sided truncus brachiocephalicus and the atresia of the left-sided arch occurs already above the separation of the left-sided arteria carotis communis. Right-sided arteria carotis communis, right-sided arteria subclavia and left-sided truncus brachiocephalicus with retro-esophageal course are

gradually withdrawing from the right-sided arch. At that time, the ductus arteriosus also leaves the left-sided truncus brachiocephalicus to form the vascular ring.

The right-side aortic arch with mirror separation of branches is the second most common variant of the right-sided arch. At that time, the left-sided arch disappears below the separation of the seventh intersegmental artery. This diagnosis is associated with up to 98% of congenital heart defects such as Fallot's tetralogy, truncus arteriosus, tricuspid atresia, and large vessel transposition with pulmonary valve stenosis [1]. By default, the diagnosis does not produce a vascular ring. The anomaly is usually associated with the left-sided ductus arteriosus, which connects the left-sided pulmonary artery and the left-sided subclavian artery but does not form a vascular ring. The right-sided ductus arteriosus is more rare. Even less frequently is described the ductus arteriosus connecting the left-sided arteria pulmonaris and the descending aorta as the remainder of the sixth left-sided arterial arch. This rare combination is already manifesting itself as a vascular ring [1, 10].

Isolation of aortic branches is a rare diagnosis based on two pathological atresia of aortic arch, separating one branch that remains connected only to the pulmonary blood circulation via the persistent ductus arteriosus [1, 11, 12]. Isolated left arteria subclavia is the most common form of aortic branch isolation and is associated in about half of the cases with other congenital heart defects. It arises from the regression of the fourth left aortic arch above and below the separation of arteria subclavia. The right aortic arch then gradually produces the left-sided arteria carotis communis, the right-sided arteria carotis communis, and the right-sided arteria subclavia. The anomaly may lead to congenital subclavian steal syndrome with vertebrate basilar insufficiency [1, 12].

Persistent Fifth Aortic Arch

The double lumen aorta is one of the rare birth defects of the aortic arch with an incidence of 1: 330 of all developmental heart defects [2, 13]. For the first time, this anomaly was described by Van Pragh in 1969, who suggested the persistence of embryonic fifth aortic arch as the caudal component of the double cavity in adulthood [14]. The persistent fifth aortic arch has two forms: systemic-systemic junction and systemic-pulmonary junction. The double lumen begins on the arch near the separation of the truncus brachiocephalicus. The systemic-systemic form of the fifth arch persistence is represented by a subsequent junction with the fourth arch at the level of the descending aorta, producing a double lumen aorta. The systemic-pulmonary form means the distal junction of the fifth arch to the sixth arch, which represents the pulmonary artery (Figure 4) [2]. Akhflash et al present three subtypes of the retained fifth aortic arch: the two-lumen aortic arch, with the two cavities permeable, the interruption of the cranial arch that arises from the fourth aortic arch, with the preserved flow through the fifth caudal aortic arch and the systemic-pulmonary fifth aortic arch [15]. A common coincidence of the preserved fifth aortic arch is coarctation of the aorta, open ductus arteriosus, bicuspid aortic valve, atrioventricular septal defect, interrupted aortic arch, pulmonary atresia, Fallot tetralogy, atresia of tricuspid valve and ventricular septal defect, although we can find in literature also isolated occurrence of this diagnosis [13, 15-17]. In the presence of a double lumen aorta as a form of persistence of the fifth aortic arch, we find two aortic lumens separated by aortic wall duplication, with no larger structures passing between them in contrast to the true double aortic arch, and no arterial branches leaving the caudal

lumen [15]. As a possible etiology of persistence of the fifth aortic arch, whether in systemic-systemic or systemic-pulmonary form, the microdeletion of chromosome 22q11.2 [1, 2] has been reported in the literature.

Figure 4. Persistent fifth aortic arch (A – systemic-to-systemic form; B – systemic-to-pulmonary form).

Not all authors acknowledge the theory that the etiology of persistent fifth aortic arch is behind the formation of the double lumen aorta [18]. Gupta et al. presented a case report analysis denying this fact. Other authors also point out that the fifth aortic arch is present only in about half of the embryos on the eleventh day of development, and its degeneration proceeds extremely rapidly towards the primitive posterior aorta [15, 18]. According to these papers, a separation proximal to truncus brachiocephalicus and a fusion with the fourth aortic arch beyond the separation of the left arteria subclavia [18] is required to establish the diagnosis of persistent fifth aortic arch. Thus, according to these and other authors, the double lumen aorta is most often caused by collateral channels around the fourth aortic arch [18-21]. Although the etiological origin of the double-lumen aorta is controversial, this diagnosis remains unconditionally a possible congenital malformation of the aortic arch without the need for intervention in its asymptomatic condition, however a possible complication in some surgical but mainly endovascular interventions.

Interrupted Aortic Arch

The interrupted aortic arch is a rare malformation with an incidence of two per 100,000 live births. It is defined by the complete disruption of continuity between the ascending and the descending aorta. The blood flow is secured by an unclosed ductus arteriosus. Symptomatology is similar to aortic coarctation symptomatology occurring during the first two weeks of life and requiring surgical intervention. Based on the location of the aortic arch interruption, we recognize three kinds of its interruption [1, 22].

In Type A of interrupted aortic arch, the arch is interrupted distally to the left arteria subclavia. Regression occurs at a later embryonic stage where the arteria subclavia is already proximal. It represents about 30-40% of all interrupted aortic arches [1].

Type B is characterized by an arch interruption between the left arteria carotis communis and the left arteria subclavia. It is formed by the atresia of the fourth aortic arch in the early embryonic phase. It is the most common form of disrupted aortic arch and is often associated with the deletion of chromosome 22q11.2 [1, 22]. It is associated with the presence of other anomalies, including the bicuspid aortic valve, subaortic stenosis, ventricular septal defect and subclavian artery anomalies [1]. Pathophysiology and manifestation are often associated with minimal left ventricular expenditure, left ventricular outflow tract obstruction and ventricular septal defect, but with preserved cerebral perfusion [22-24].

In type C, the aortic arch atresia is most proximal, that is, between the truncus brachiocephalicus and the left arteria carotis communis. It is manifested in the development defect of the most proximal part of the fourth and the third aortic arch [1]. It is extremely rare and represents only 5% of all aortic arch interruptions [1, 22].

AORTIC ARCH ANEURYSM

In December 1948, Rudolph Nissen at the Brooklyn Jewish Hospital in New York operated Albert Einstein for the thoracic aortic aneurysm. Due to the extent of the finding and the possibility of the then thoracic aortic medicine, the surgeon just covered the ventral two thirds of the aneurysm with yellow cellophane. Albert Einstein then lived for 6 years until an aortic wall rupture occurred [25]. Today's medicine offers for this diagnosis a number of progressive solutions with relatively optimistic post-operative results.

Indications for urgent aortic aneurysm surgery include its rupture, pseudoaneurysm, and aortic dissection, which will be discussed below. Indications for elective aneurysm surgery are an enlargement of the aortic diameter by more than 1cm per year, a diameter above 6cm and a diameter above 5cm in patients who are indicated for surgery for an ascending or descending aortic aneurysm, or in patients with Marfan syndrome or a positive family history of rupture or dissection [3].

Medical history should be taken into account when examining the patient. The family history of this disease is relatively frequent and may confirm to the surgeon an indication of surgery in borderline situations [26]. Computerized tomography and magnetic resonance imaging are recommended as imaging methods, both with appropriate contrast media. Coronary angiography and ultrasound examination of the heart are also indicated in view of the incidence of disease in the elderly in order to consider concomitant cardiac surgery on the heart [3]. In a patient indicated for elective surgery, a thorough examination of the supraaortic branches of the aorta is required to identify patency of both arteriae carotis communis and arteriae carotis interna as well as arteria vertebralis. In the case of a positive personal history of stroke, computerized tomography of the brain is further indicated to determine the extent of damage and the possibility of post-operative comparative examination at the clinical manifestation of neurological complications [3].

Anesthesia in aortic arch surgery is similar to anesthesia in cardiac surgery. Standard monitoring should include invasive measurement of pressure on arteria radialis and arteria

femoralis, Swan-Ganz catheter and central venous catheter. Perioperative transesophageal echocardiography is recommended to monitor the ejection fraction and satisfactory flow in the aortic arch. Some workplaces also use perioperative encephalography. Our workplace uses cerebral oximetry in correlation with other works to monitor the correct selective cerebral antegrade perfusion. This allows for consideration of the conversion of unilateral selective cerebral antegrade perfusion to bilateral due to insufficient anatomical conditions as well as early detection of possible complications, including catheter blockage or its migration [27]. Another option, which is also not used in our workplace, is the transcranial Doppler examination, which brings with it increased dependence on the expertise of the investigating physician. Cohn et al. recommend an initial dose of 1g of methyl prednisone when initiating extracorporeal circulation, assuming a duration of hypothermia of more than ½ hour followed by a repeated dose of 125mg four times within the first 24 hours and then every 12 hours on the second postoperative day [3, 28].

For perfusion, the protocol used in cardiac surgery can be used. After cannulation of the right-sided arteria axillaris, an extracorporeal circulation is triggered. Echocardiographic monitoring is recommended, especially in field of dissection. In surgical procedures involving also the descending aorta, a concomitant cannulation of the arteria femoralis for perfusion of the lower half of the body and shortening the necessary length of the arrest is a useful method. The non-pulsatile flow during extracorporeal circulation increases cerebral vascular resistance, leading during the operation to an increase in the pressure required for sufficient perfusion of brain tissues and maintenance of satisfactory cerebral oxygenation. Furthermore, in correlation with other workplaces, in our workplace we use local cooling of head by applying ice [3]. Other specificities of cerebral protection during surgery will be discussed below.

Medial sternotomy, as a gold standard for cardiac surgery approaches, provides sufficient visualization of the ascending aorta, the aortic arch, and the proximal portion of the descending aorta about 5 cm behind the separation of the left-sided arteria subclavia. In case of need, the incision may be further extended along the edge of the left sternocleidomastoid muscle. Further, the visualization is limited by the course of the vena brachiocephalica sinistra, which can be interrupted if necessary and reconstructed at the end of the operation. If aortic involvement requires resection of a larger part of the aorta, thoracosternotomy or bilateral anterior thoracotomy is useful as a surgical approach, however it carries higher risks of postoperative respiratory insufficiency and phrenicus nerve damage [3, 29].

In spite of the rapidly developing endovascular technique also in the field of the aortic arch, the open surgical approach remains a still used strategy. Hui et al. report very optimistic results of open aortic surgery with a 30-day mortality of 5% to 9.7% and an incidence of stroke from 2.8% to 6.2% [5]. Thus, the carrier theme remains cerebral perfusion during surgery.

Cerebral Protection Strategies in Aortic Arch Surgery

One of the most important components of aortic arc surgery is to maintain circulation in the supra-aortic branches to prevent perioperative hypoperfusion of the brain. The patient undergoing this surgery is at risk of developing neurological complications and the management of the entire operation must be tailored to minimize this risk. However, there is

not known any universally and unambiguously most optimal solution, and several modifications of individual steps for patient protection are therefore discussed. Early attempts at both aortic and descending aortic surgery were accompanied by frequent hypoxic peripheral organ damage and neurological deficits. Systemic hypothermia was one of the first methods of neurological protection during circulatory arrest. The first study involving aortic arch reconstruction using deep hypothermia with circulatory arrest dates from 1975 [30]. Subsequently, methods of selective antegrade and selective retrograde brain perfusion using less deep hypothermia were introduced.

Circulatory arrest in the head and the brain was an unconditional part of aortic arch replacement in the past. Circulation interruption time is called “circulatory arrest” and provides bloodless vessel manipulation and the possibility of sewing its anastomosis. We divide two types of neurological complications of these operations, permanent neurological damage and temporary neurological damage. Permanent neurological damage, also referred to as perioperative stroke, is due to the embolism of a solid particle, most commonly a piece of atherosclerotic plaque, or bubble to vessels supplying brain tissue, resulting in ischemic sudden stroke in its basin. On the other hand, temporary neurological involvement does not have an anatomical correlate and is due to insufficient brain tissue perfusion at the time of surgery. Computer tomography or magnetic resonance imaging is most often negative in this case and clinical manifestation is only due to global cerebral ischemia [31]. Thus, to ensure the protection of both organs and the brain, the temperature of the organism and tissues is reduced during circulation to reduce the metabolic demands of the individual organs. Brain tissue has significantly higher metabolic requirements than other tissues. Today we know that when the body temperature drops to 15 degrees Celsius, the metabolic demands of the brain are reduced to only 84% [32]. Griep et al. in their time declared that lowering body temperature is a sufficient protective method of protecting neurological tissue with excellent results [30]. Currently there are used several techniques of the most frequently combined application of hypothermia and selective perfusion of neurological tissues [31].

Deeply hypothermic circulatory arrest without or with selective perfusion of some tissues is the simplest form of cerebral protection. In principle, it does not need monitoring of brain perfusion and is a popular access strategy for surgeons and workplaces where aortic arc surgery is not a frequent surgical procedure. After connecting the patient to extracorporeal circulation, the patient's cooling phase is provided by cooling the blood with a heat exchanger. It is important to keep the heat gradient between venous blood aspirated from the patient's body and arterial blood from the extracorporeal circulation less than 10 degrees Celsius, which prevents air bubble formation. The overall duration of patient cooling and preparation for surgery itself is thus dependent on multiple parameters including extracorporeal circulation blood flow, temperature gradient, but also the patient's weight and tissue specificities. Although the method is not dependent on special investigative techniques, monitoring parameters such as time, temperature, venous oxygenation, and electroencephalographic activity increases the patient safety. The temperature is monitored both at the inlet and the outlet of the blood from the extracorporeal circulation as well as in the individual tissues, most often in the esophagus, bladder and rectum. Using hypothermia without another method of brain perfusion, arrest may be initiated on the basis of esophageal or nasopharyngeal temperature, due to the correlation of temperatures in this site with brain tissue temperature. In general, it is recommended to reach a temperature between 14.1 and 20 degrees Celsius. When the temperature limit is reached, the extracorporeal circulation is

stopped, allowing to operate in a bloodless environment. After the completion of the necessary phase of reconstruction, the extracorporeal circulation and circulation are restored after careful removal of the vascular gas from vascular basin [31]. Initial works targeted at aortic arch reconstruction used this protection in isolation [30]. Nowadays, in order to provide sufficient neurological protection in isolated use of deep hypothermal arrest, the recommended duration of the arrest is 40 minutes [31, 33, 34]. Svensson et al. report mortality of 6.3%, incidence of sudden stroke of 4.8%, need of dialysis of 2.3% in isolated use of arrest in deep hypothermia, with mean duration of arrest in group of 31 minutes [33]. The authors further point to a sudden upward trend in the risk of developing a sudden stroke in excess of 40 minutes of arrest [33]. Thus, complex performance has led to the introduction of a combined cerebral protection strategy [31].

The history of using retrograde cerebral perfusion is not associated with aortic arc surgery but with the treatment of iatrogenic massive air embolism [35]. Retrograde perfusion is performed by applying cold oxygenated blood to the upper vena cava, what leads to the perfusion of the upper half of the body, including the brain, in the retrograde direction. Universally, blood is applied at a flow rate of 200 to 400 mL/min, giving a pressure of 15 to 25 mmHg [31]. Correct application can be verified by draining dark deoxygenated blood from the arterial system of the upper half of the body. The method has several positives. First of all, it is the ability to wash out mechanical embolisms from the arterial circulation of the brain, then maintenance of controlled hypothermia of the brain, and, last but not least, promotion of brain metabolism by the continuous application of oxygenated blood. The combined use of deep hypothermia and retrograde cerebral perfusion thus provides better results and a lower risk of neurological complications following surgical performance on the aortic arch. Coselli and Lemaire compared the effectiveness of isolated deep hypothermia and combined hypothermia with retrograde perfusion in 479 patients. The authors report that the combination with retrograde cerebral perfusion significantly reduces mortality and the risk of sudden stroke [36]. Other authors document that supplementing hypothermia with retrograde cerebral perfusion has a significant protective potential for sudden stroke and mortality [37]. Despite these positive results, the incidence of insufficient cerebral protection is still present and the mortality rate, even when using the combined approach, is 3.4% [36].

Another method of reducing the risk of neurological complications during aortic arc surgery is selective antegrade cerebral perfusion, first described by De Bakey et al. [38]. It is generally accepted that antegrade blood flow will provide more effective oxygenation of brain tissues compared to retrograde flow when oxygenated blood is applied via the upper hollow vein. Technically, this method is feasible by several modifications. Bilateral application is universally performed by the application of oxygenated blood to the left arteria carotis communis and truncus brachiocephalicus after the opening of the aortic arch. The risk lies in the air embolism as well as in the embolism by the solid particles released from the atherosclerotic plaques during cannulation. In addition, the cannulae increase opacity in the operating field. Several authors, including our workplace, prefer selective antegrade brain perfusion by applying oxygenated blood to the right arteria axillaris [39-41]. The operation begins with sutura of 8mm end to side vascular prosthesis on the right-sided arteria axillaris, into which is inserted the arterial extracorporeal circulation line (Figure 5). The venous line is introduced either via the vena femoralis pathway or through the right atrial ear as standard. During the arrest, the truncus brachiocephalicus and the left-side arteria carotis communis are clamped and the extracorporeal circulation is reduced to approximately 10mL/kg/min. The

flow is further adapted to the depth of hypothermia. The pressure can be monitored by cannula introduced into the right-sided arteria radialis. Left hemisphere perfusion is ensured by collateral circulation (Figure 7). At its insufficiency perfusion of this part of the brain is at risk and selective perfusion must be supplemented with another arterial cannula applied directly to the left-sided arteria carotis communis. However, the papers show that right side cannulation of the arteria carotis communis is not necessary for intact Willis circuit [42-44]. Moreover, manipulation of the right-sided arteria carotis communis may increase the incidence of perioperative sudden stroke [45].

Figure 5. Axillary artery cannulation by using of 8mm vascular prostheses (AA – axillary artery; AV – axillary vein).

The use of selective cerebral perfusion makes it possible to replace deep hypothermia with a milder form. Total arrest is converted to lower body arrest using selective brain perfusion and low temperature is designed to protect other organs, peripheral tissues, and spinal cord. The lower metabolic demands of these organs impose lower demands on hypothermia and metabolism compared to the brain. The combination of appropriate hypothermia and selective antegrade brain perfusion is currently a popular standard used worldwide, even in our center [31, 41]. For half-arch replacement, hypothermia at 28 to 29 degrees Celsius is recommended, with studies presenting a mortality of 4.3% for elective procedures and 7.7% for emergent procedures, a transient neurological deficit of 1.9% for elective procedures, and 4.6% for emergent procedures, an incidence of sudden stroke 3.8% for elective surgery and 6.2% for emergent surgery and incidence of renal failure 2.4% for elective and 9.2% for emergent surgery [40]. At full arch replacement, the studies recommend a temperature of 25 to 26 degrees Celsius and demonstrate a mortality of 9.7%, an incidence of transient neurological disorders of 2.8%, a sudden stroke of 5.6%, and a renal failure with a need for dialysis of 2.8% [46-49].

Due to the habits of different workplaces, there are currently no universal rules for using cerebral protection. The parameters and differences of the selected protection include several

basic parameters, to which belong the site of the arterial line cannulation of the extracorporeal circulation, the target temperature of the selected hypothermia, the use of antegrade or retrograde selective cerebral perfusion, and the use or non-use of bilateral antegrade perfusion. Although some studies compare two methods to some extent, a complete randomized study has not been performed to definitively compare the benefits and limitations of all methods and the choice remains more focused on workplace habits than objective results. When using several methods at one workplace, we most often encounter the use of deep hypothermia with retrograde cerebral perfusion and moderate hypothermia combined with antegrade selective cerebral perfusion [31]. Chen et al. conclude this subject with two arguments. First and foremost, the combination of hypothermia with selective cerebral perfusion is a method superior to the use of isolated hypothermia that produces better results. Further, on the one hand, the choice of antegrade or retrograde selective perfusion does not affect the incidence of sudden stroke, but on the other hand, the use of antegrade choice decreases the incidence of transient neurological postoperative complications [31, 50-52]. Our experience prefers standard right-sided axillary artery cannulation and continuous monitoring of cerebral saturations. At insufficient cerebral saturation, we then recommend the addition of bilateral selective cerebral perfusion. If it is not possible to use this technique, which represents anatomical malformations such as aberrant right subclavian artery, damage to the proximal part of the right subclavian artery by dissection or stenosis, then it is necessary to look for an alternative in the spectrum of the above-mentioned procedures.

Safi et al. present in a group of 117 patients undergoing the first period of operation by elephant trunk procedure presents 5.1% 30-day mortality [53]. Interestingly, according to the study, 37% of patients did not undergo the second part of surgical performance on the descending aorta [53]. Other authors present 8% mortality after identical surgery [54]. Coselli et al. in the group of 227 patients present 6% early and 9% late mortality with only a 3% incidence of sudden stroke and a relatively low incidence of other neurological consequences [55]. Other minor studies also show relatively low perioperative and moderate long-term mortality [3, 56, 57]. Cohn et al. present a group of 206 patients undergoing electively aortic arch surgery, giving an average arrest time of 30 minutes and subsequent hypothermia of 69 minutes. As the most common etiology, they report chronic dissection and atherosclerosis. To risk factors Cohn et al. assign chronic obstructive pulmonary disease, insulin-dependent diabetes mellitus, hemodialysis and reoperation [3]. The authors report 6.8% of hospital mortality with a risk of sudden stroke at the level of 3.3%. The most common postoperative complications included long-term intubation, transient neurological deficiency, reoperation for bleeding and temporary or permanent renal failure. The stay in the intensive care unit was on average 3 days and the hospitalization time after the surgery was 11 days [3].

AORTIC ARCH DISSECTION

Aortic dissection is a condition in which a tear in the lamina intima of the aortic wall leads to the redirection of the blood stream into the aortic wall. Thus, a false lumen for blood flow is formed between the intima and the medium. The acute forms of each dissection type carry high lethality. In the Stanford classification we distinguish type A dissection, where the intimal tear occurs in the ascending aortic site and type B when the tear is located in the

descending aorta (Figure 6) [3]. In this chapter, we will only deal with the acute form of type A dissection.

Figure 6. Type A, and type B of Stanford aortic dissection classification according to the position of the dissection originate.

Acute dissection type A is a disease with high mortality. Half of the patients die within 2 days from the onset of disease [58]. Some studies suggest that mortality increases by 1% every hour when not diagnosed. The high mortality rate of delayed diagnosis confirms that this disease should be considered in every suspected symptomatology. In hemodynamically unstable patients suspected of having a pericardial tamponade or hemorrhagic shock, transport to the operating room is indicated. Investigations and operations such as transesophageal echocardiography or the introduction of a central venous catheter are only indicated in the operating room, possibly under general anesthesia, for the risk of hypertension in painful exercise. In the first step it is necessary to fulfill the conditions for the possibility of immediate pericardiotomy and the connection of the patient to extracorporeal circulation [3].

In hemodynamically stable patients, it is important to measure the pressure on both upper limbs and stabilize it to a higher measured value. Stabilization of arterial pressure is necessary to reduce transmural stress in the aorta wall and reduce the risk of rupture, as well as to prevent further propagation of dissection by reducing the pressure in the false lumen. Thus, stabilization of systolic pressure between 90 and 110 mmHg at a heart rate of up to 60 beats per minute is necessary [59]. Equally important is pain therapy to reduce catecholamine leaching. Thus, conservative therapy in stable patients includes opioids, beta-blockers, vasodilators, particularly nitrates. In the contraindication of beta-blockers, the drug of choice are calcium channel blockers [3].

The aim of an urgent operation is to prevent the emergence of a state incompatible with life by redirecting blood flow to the right lumen. Complications of dissection resulting in patient death include rupture of the aortic wall into the pericardial or pleural cavity,

dissection, or closure of coronary arteries and acute aortic valve regurgitation of the severe grade. The contraindication of acute surgery is not the age or the current neurological status of the patient, due to the possibility of his improvement after the blood flow redirection and the stabilization of hemodynamic parameters. Also, the time lag from the first symptoms or the symptoms of false lumen thrombotization do not guarantee the non-development of further complications of the condition and thus do not cause the operation to be unindicated. Some works in these situations prefer elective performance without undue delay instead of emergent performance [3, 60]. The aim of the surgery is to replace the aorta in the extent of its disability, to rehabilitate the complications and to thoroughly control the blood flow redirection to the right lumen.

SURGICAL PROCEDURES

For both the aneurysm and dissection of the thoracic aorta, we choose a similar surgical strategy to try to replace the entire affected aorta. An alternative is to prepare the distal portion of the affected tissue for the next endovascular procedure, or surgery on the thoracoabdominal aorta. In this chapter, we will discuss the most commonly used surgical procedures on the aortic arch, often combined with intervention on the ascending aorta and aortic root. The next chapter then focuses on procedures unconditionally followed by endovascular performance directly on the aortic arch.

Bentall Procedure with Hemiarch Replacement

Bentall half-arch surgery is a surgical procedure indicated for aortic valve involvement with an aneurismal enlargement of the ascending aorta intervening the first half of the aortic arch. As a surgical approach, we choose medial sternotomy and cannulate predilectionally the right-sided arteria axillaris and the right atrium via right atrial ear. During the preparation of hypothermia, we have the possibility of preparation of the surgical field with the determination of the extent of surgery. In this phase, the whole-body perfusion is ensured by the arteria axilaris. On the transverse clamp of the ascending aorta, we most often use antegrade cardioplegia applied selectively to the coronary orifice intermittently. If necessary, retrograde cardioplegia can also be applied via the sinus coronarius. Myocardial protection is supplemented by local ice cooling. Further, the aortic root and the coronary artery orifice with the target are prepared. Most often we use a mechanical valve conduit with a tubular prosthesis, the size being chosen according to anatomical conditions. As an alternative, a combination of biological prosthesis with tubular prosthesis is offered in elderly patients. The conduit is fixed to the aortic position by the intraannular method of individual stitches on the pads, the choice of conduit of 1 to 2 mm narrower than the measured aortic ring size is important. In the case of unsatisfactory anatomical conditions, a supraannular fixation is possible when the conduit should correlate with the measured aortic ring size. Subsequently, we perform the coronary artery suture into the conduit.

Figure 7. Blood flow after axillary artery cannulation and supraaortic branches clamping.

Once the appropriate degree of hypothermia has been reached, the performance can be extended to intervene on the aortic arch. Cohn et al. recommend arrest only after reaching the esophageal temperature of 18 degrees Celsius and oxygenation in vena jugularis 95% [3]. Then is placed a clamp on the truncus brachiocephalicus, the left arteria carotis communis and the left arteria subclavia. The aortic clamp can be removed, and the aortic arch revision is possible. The upward aorta and proximal part of the aortic arch are excised. On convexity, the incision is proximal to the separation of the truncus brachiocephalicus, then on the concavity of the arch intimately proximal to the separation of the ligamentum arteriosum while maintaining the nerve laryngeus recurrens. The technique of distal anastomosis between the tubular prosthesis and the aortic arch is chosen according to the quality of the aortic wall. A sandwich technique is recommended where the graft is invaginated inside the aorta, which is also covered by a Teflon pad outside [61]. Another option is to use an implantable felt, which also meets hemostatic demands. After completion of anastomosis and venting of the aortic arch, the implanted prosthesis is then clamped and the whole-body perfusion is restored. After re-circulation, isothermia can be gradually restored. The last suture is the suture of both prostheses with subsequent venting of the heart cavities and reperfusion. Disconnection from the extracorporeal circulation is possible after reaching the isotherm. When the aortic root is not affected, the performance can be limited to the supracoronary replacement of the ascending aorta with aortic half-arch replacement (Figure 8).

Figure 8. Supracoronary replacement with hemiarch replacement.

Elephant Trunk Procedure

Primarily, the elephant trunk procedure was designed as a surgical solution to the aortic arch aneurysm followed by surgical treatment of the thoracic descending or toracoabdominal aorta from the left-sided thoracotomy approach [25]. Despite the preferred endovascular approaches, the descending aortic aneurysm of larger dimensions remains the primary diagnosis for surgical open intervention.

As such, the technique offers both the possibility of a concomitant operation and the approach in two separate steps, with the second step selecting a surgical or endovascular approach. However, the independent sternotomy makes the current visualization of both the ascending and the descending aorta very complicated. However, two-stage surgery carries the risk of bleeding in field surgery after primary surgery [54, 62]. The main advantage of this technique is that, after the primary operation, a prosthesis is left in the descending aorta that extends significantly below the site of the primary surgery suture (Figure 9). Thus, the anastomosis itself is performed in the second step in a safe healthy tissue of the descending aorta. The second unavoidable advantage in the second step is the possibility of clamping the graft itself, which minimizes perioperative bleeding and the possibility of a perioperative rupture of the aortic wall [62, 63].

The indication is the extent of thoracic aortic involvement requiring intervention on the aorta of two surgical approaches, assuming that the replacement of the aorta and the arch made from sternotomy will be complemented by surgery on the descending aorta from the lateral thoracotomy approach [25]. The indication may be more frequently an aneurysm but

less often a thoracic aortic dissection. Thus, in more than 90% this procedure is indicated electively [54, 63, 64].

Figure 9. Elephant trunk procedure.

The introduction of the operation copies the procedure for half arch replacements. The extracorporeal circulation is introduced via the left arteria axillaris and the right atrial ear. Vena femoralis remains the choice. Immediately after initiating the extracorporeal circulation, we start with hypothermia of the patient. The procedure on the ascending aorta and the root of the aorta is chosen according to the extent of the affection of this anatomical site. Both Bentall and David or Yacoub surgery, as well as supracoronary replacement of the ascending aorta without intervention on the aortic root [41, 65], are considered. Upon achieving appropriate hypothermia, we switch to selective upper body perfusion. If the aortic wall is not affected in the locality of separation of supra-aortic branches, we can leave these on one target, where a linear prosthesis can be used for the elephant trunk technique with sewing the supra-aortic branches as an only target. With the need for tissue exclusion between the supra-aortic branches, more often with aortic dissection, we prepare each of the three supra-aortic branches selectively and select the graft with prefabricated separations for the suture of these arteries. The distal suture is performed at the boundary of the passage of the aortic arch and the descending aorta, while maintaining the nervus laryngeus recurrens. Distal anastomosis is performed on an invaginated prosthesis inserted into the descending aorta. After the suture is completed, the inner part of the prosthesis is exvaginated. The outer part remains definitively retracted in the descending aorta ready for performance from the lateral thoracotomy

approach. Subsequently, we perform a suture of the supraaortic branches according to the chosen preference and prosthesis. Further, it is possible to put the clamp on the prosthesis, trigger the perfusion of the whole body of the patient and heating of the patient. Thus, the final steps are the proximal suture according to the desired extent of resection and disconnection of the patient from the extracorporeal circulation.

The distance between surgical intervention of sternotomy and thoracotomy varies considerably, mainly according to the extent of aortic involvement and fragility of the descending aorta structures, which correlates with the risk of its rupture or dissection by postponing the second step of the procedure. In the literature, we find time intervals of one hour to 60 months from primary surgery [25, 62, 64]. The specific operating procedure will be described in the chapter dedicated to the descending aorta.

A variant of this operation is the reverse elephant trunk, where the primary operation is performed on the descending aorta, leaving the invaginated prosthesis. In the performance of the aortic arch, after the visualization and the incision of the aortic arch, we find an invaginated graft in the descending aorta, which we exvagate and the operation proceeds as standard. Reverse elephant trunk technique is indicated especially in congenital developmental defects of the descending aorta, where this part of the aorta is more risky for possible rupture than the aortic arch.

Johnson et al. report the following possible complications of this procedure: graft closure, graft kinking, neurological complications, mediastinitis, need for tracheostomy, renal insufficiency, thoracotomy requiring hemorrhage, death, clot formation around distal anastomosis, peripheral thromboembolism, paralysis of nervus laryngeus reccurens and complete paralysis of vocal cords [25].

Frozen Elephant Trunk Procedure

If the indication for elephant trunk is more often aneurysm in thoracic aorta, then in frozen elephant trunk it is mainly the dissection in this site. Frozen elephant trunk differs from the soft variant so that a portion of the prosthesis distal to the distal anastomosis with the aorta is not formed by the vascular prosthesis but by the stentgraft. The dissection progressing to the descending aorta and any other tears in the intimal layer at this site are so occluded by the stentgraft. In addition, this anatomical modification, while still more distal to the dissection progression, permits direct establishment of endovascular therapy on this prosthesis. Currently used prostheses allow the suture of supra-aortic branches both on one target when this portion of the aorta is not affected and also separately on the prefabricated separations of the prosthesis which additionally has a fourth vascular prosthesis for application of cardiopulmonary bypass.

ENDOVASCULAR A HYBRID PROCEDURE ON AORTIC ARCH AND DEBRANCHING TECHNIQUE

Despite the simultaneous progression of techniques increasingly favoring separate endovascular procedures also on the aortic arch, hybrid performance is still preferred in this

site. Hybrid performance is a fusion of benefits of both the open surgery and the endovascular procedures, offering the patient an optimal result. Hybrid performances on the aortic arch can in principle be divided into several types explained in the following subchapters. The Ishimaru classification introduced in the chapter devoted to anatomy is used as an anatomical guide.

Table 1. Selected series of hybrid arch repairs [5]

Years of study/study	N	30 days or in hospital mortality	Stroke	Retrograde dissection	Reintervention	Survival/follow up
2003-2011[66]	66	9%	5%	3%	14%	72%/5years
2005-2012[67]	47	8%	8%	2.7%	2.7%	48%/5years
1997-2009 [68]	47	19%	6.3%	6.3%	27.6%	59%/3years
2005-2011 [69]	29	6.9%	10.3%	0%	6.9%	79%/1.5year
2005-2008 [70]	28	0%	0%	0%	7%	70%/3years.
2005-2010 [71]	27	11.1%	0%	0%	0%	78%/1.5year
2005-2009 [72]	27	11%	11%	-	0%	-

Mortality of hybrid performance in aortic arch is 6% to 11%. Studies containing a higher percentage of emergent procedures present higher mortality [5, 68]. However, the input sets of the individual files vary considerably in parameters such as the stentgraft loading direction and the left subclavian artery revascularization. Multicenter studies present comparable results of open surgical methods and landingzone-0 targeted hybridization methods [73]. Further studies present also comparable results of both techniques with slightly better results of the open surgical solution in parameter of 30day mortality [74]. Importantly, in postoperative follow-up, statistically significantly benefit patients treated with open surgery with a lower risk of developing a new aortic episode [5]. In conclusion it can be stated that groups in either study or multivariate analysis are not fully comparative, and each group contains also patients completely unsuitable for another type of performance. An endovascular approach is associated with a lower risk of post-bleeding, an open surgical approach with a lower incidence of spinal cord injury. Thus, the surgeon or angiologist should modify the procedure both on the basis of the particular patient and on the practice and experience of the particular workplace [75].

Hybrid Arch Type I Repair

In the field where the aneurysm is limited only to the aortic arch, at the intact ascending aorta and the Z3/4 zone of the Ishimaru classification, we can ensure the passage of the supraaortic branches by their debranching into a healthy ascending aorta (Figure 10). One branched prosthesis is most often used for this purpose. In the case of a specific situation and the inability to revascularize the supra-aortic branches by this most frequent way, other options discussed below come into consideration [5].

Figure 10. Debranching of the truncus brachiocephalicus and left arteria carotis communis with extraanatomical bypass to left subclavian artery and ligation of its proximal part in the field of unaffected landing zone Z0.

The risk of developing endoleak and retrograde dissection is due to considerations of stentgraft implantation to use the 0-Ishimuru zone as the basic landing zone. Surgical revascularization of supraaortic arteries remains a condition, either by transposition or bypass. The need for this revascularization is also encountered in the need to overlap the separation of the truncus brachiocephalicus, or when the diameter of this branch is not sufficient to revascularize the entire upper half of the body [5]. With good condition of the ascending aorta, it is possible to perform complete debranching without the use of extracorporeal circulation through medial sternotomy using the partial clamp of the ascending aorta. There is a number of variations in this revascularization. It is necessary to consider the status of the ascending aorta, the risk of stenosis of the supra-aortic branches as well as the postoperative complications of the sternotomy itself [5, 76]. After revascularization of the supraaortic branches, ligation or coiling of the original separations is recommended as a prevention of later endoleak [5].

Hybrid Arch Type II Repair

In the field, when the aneurysm reaches also the ascending aorta, namely the Z0 zone of Ishimaru classification, simple stentgraft implantation is not possible, even after the debranching of the supraaortic branches, especially due to the high risk of retrograde dissection of the ascending aorta. Thus, the ascending aorta must be by cardiosurgical

intervention using extracorporeal circulation replaced by a prosthesis with implanted separations of supraaortic branches of the aorta [5].

Figure 11. Supracoronary replacement of ascending aorta with debranching of all supraaortic branches.

In the field of affection of the ascending aorta provided that the patient tolerates extracorporeal circulation, is indicated a supracoronary replacement of the ascending aorta, possibly Bentall surgery with the debranching of the supraaortic branches into the vascular prosthesis. Thus, the supra-aortic branches withdraw from the prosthesis or several consecutive vascular prostheses (Figure 11). The procedure greatly eliminates the risk of retrograde endoleak [5].

Hybrid Arch Type III Repair

This type represents the aneurysmal distribution of the ascending aorta, the aortic arch and the descending thoracic aorta. It is therefore necessary to solve the whole course of the thoracic aorta. Surgical open substitution of the ascending aorta and the aortic arch with elephant trunk implantation or frozen elephant trunk followed by endovascular intervention of the descending thoracic aorta with direct stentgraft attachment to elephant trunk prosthesis or stentgraft frozen elephant trunk are recommended [5].

Management of Supraaortic Branches and Left Subclavian Artery Dilemma

Extraanatomical bypasses at this site are usually a solution if the aneurysm reaches the proximal edge of the truncus brachiocephalicus or the left arteria carotis communis. The

management of the left arteria subclavia and the left arteria carotis communis can generally be solved without the need for sternotomy by the incision on the neck. The carotid-subclaval bypass allows the Z2 anchoring zone to be used in the second step. Expansion of extraanatomical bypass between both arteria carotis communis allows the intervention angiologists to use also the Z1 zone [5]. Sequence transposition via hemisternotomy is also used. The debated issue is the necessity of maintaining the revascularization of the left arteria subclavia. Recent recommendations by Society for Vascular Surgery recommend continuing to revascularize the left arteria subclavia in planned procedures but leave the surgeon to decide on the perioperative findings in emergencies [5, 77, 78]. In planned interventions of this type it is necessary to perform pre-operatively the arteriography of cerebral arteries including the Willis circuit. It is important to exclude whether the left arteria thoracica interna is used for myocardial revascularization, the absence of the right arteria vertebralis, the carotid stenosis, and the incomplete Willis circuit. The potential for use of the left arteria subclavia in type I endoleak therapy is a fact against the revascularization of this artery during primary surgery. On the other hand, the risk of ischemia with the need for secondary revascularization, type II endoleak and the onset of sudden stroke in hypoperfusion of the left arteria vertebralis [5, 79], is increased in the case of non-vascularization. Hui et al. conclude this by stating that the incidence of sudden stroke is the same in physiological intracerebral circulation, as in the revascularized and occluded left arteria subclavia (4.6% vs 3.6%) [5].

Total Endovascular Approaches and Future Directions

Significant development of endovascular techniques in the abdominal aortic site has also led to the development of methods aimed at the thoracic aorta and the aortic arch. Phenestrated stentgrafts, stentgrafts with branches for supra-aortic branches of the aortic arch are put into practice at the time of this publication. The development of these methods opens the possibility of independent endovascular therapy of aortic arch diseases. However, recent studies still offer only small groups of patients, rather reminiscent of case studies with only short-term follow-up [5, 80, 81]. Further studies will show if this modality offers a new pathway in the treatment of aortic arch diseases.

Chapter 286

DESCENDING AND THORACOABDOMINAL AORTA

Tomáš Toporcer*, MD, PhD

Department of Heart Surgery of East Slovak Institute of Cardiovascular Diseases,
Pavol Jozef Safarik University, Kosice, Slovakia

ABSTRACT

After the anatomical summarizing, the first part of the chapter deals mainly with congenital developmental defects of the descending aorta, including mainly various forms of right-sided aortic arch, but also patent ductus arteriosus and aortic coarctation. The next part of the text summarizes the current knowledge of aneurysm and dissection of the descending aorta. The third part is then focused on surgical procedures in this part of the aorta, including various forms of lower half of body perfusion during surgery. In the end, attention is drawn to the traumatic lesions of the descending aorta.

Keywords: descending aorta, aortic aneurysm, aortic dissection, descending aorta injury

ANATOMY OF THE DESCENDING AORTA

The descending thoracic aorta begins distal to the left arteria subclavia spacing at the level of the third to fourth thoracic vertebra and ends at the level of the twelfth rib where it passes through the hiatus aorticus diaphragm [1]. In the cranial course, it touches the chest vertebrae from the front left. More caudally, it gets to the medial plane. In front of the aorta is the esophagus and the heart. To the left of the aorta is the vena hemiazygos, to the right the vena azygos. The ductus thoracicus protrudes between the aorta and the esophagus and the parietal pleura touches it bilaterally from the lateral side. Branches of this part of the aorta include arteriae intercostales posteriores and arteria phrenica superior, as parietal branches. Further are rami bronchiales, rami oesophagei, rami pericardiaci and rami mediastinales, as visceral branches [2]. The Adamkiewicz artery (ramus spinalis aortae) is another clinically

* Corresponding Author's Email: topyto@gmail.com.

important branch of the descending thoracic aorta and it is the main branch for spinal perfusion in this locality. There is significant variability at it, either from intercostal arteries at the level of the 9th to the 11th intercostal space, or directly from the aorta [1].

The descending abdominal aorta is a continuation of the thoracic part, beginning with the passage of the aorta through the diaphragm and ending at the level of the fourth lumbar vertebra by bifurcation on the arteriae iliacae communes. The entire abdominal aorta lies retroperitoneally. On the right of the aorta is the vena cava inferior and, on both sides, we find lumbar lymph nodes. In this course, the aorta gives off the arteria phrenica inferior and arterie lumbales as parietal branches. As the visceral branches are then paired the arterial suprarenales mediae, arteriae renales and arteriae testiculares or ovaricae and unpaired the truncus coeliacus, arteria mesenterica superior and arteria mesenterica inferior [2].

CONGENITAL MALFORMATIONS

The most common congenital malformations and descending aortic developmental disorders include the anomalous separation of the right arteria subclavia - with or without diverticulum of Kommerell, bilateral ductus arteriosus, coarctation and pseudocoarctation of the descending aorta. All these malformations are related to embryogenic disorders [3].

Left Aortic Arch with Aberrant Right Subclavian Artery

The left aortic arch with aberrant right subclavian artery is the most common congenital developmental disorder of the thoracic aorta with an incidence of 0.5% - 2% [3, 4]. The anomaly arises from the regression of the right-sided arch between the right arteria carotis communis and the right subclavian artery. Thus, the right posterior aorta forms the definitive retro-esophageal portion of the right subclavian artery. The aberrant right subclavian artery is thus the most distal large branch of the thoracic aorta with typical retroesophageal course to the right cranially. The anomaly is typically isolated, less frequently it can be associated with aortic coarctation, patent ductus arteriosus, ventricular septal defect, or vertebral artery anomalies. In Down syndrome patients it is present in up to one-third of patients. Typically, the malformation is asymptomatic, without necessity of intervention, only about in 10% it can cause esophageal suppression with a typical symptom of dysphagia lusoria [3, 4].

Left Aortic Arch with Diverticulum of Kommerell

The diverticulum of Kommerell is the descending aortic aneurysm at the site of separation of aberrant subclavian artery (Figure 1). It is the remnant of the right-sided posterior primitive aorta. This rare diagnosis was first described by Kommerell in 1936, in a case report of a patient with left-sided aortic arch and diverticulum in the proximal course of the descending aorta [5]. Despite the specific first description, the name Kommerell diverticulum is now used for the descending aortic aneurysm, from which separates the aberrant subclavian artery, either at the left or at the right aortic arch. At the incidence of

aberrant subclavian artery in 0.8% to 2% of the population and the fact that the diverticulum of Kommerell is present in 20% to 60% of these separations, a total incidence in more than 0.5% of the population can be expected [6-10].

Figure 1. Kommerell diverticulum with aberrant right subclavian artery (LCCA – left common carotid artery; LSA – left subclavian artery; LVA – left vertebral artery; KD – diverticulum of Kommerell; RCCA – right common carotid artery; RSA – right subclavian artery; RVA – right vertebral artery).

The fact remains that only 5% of patients with diverticulum of Kommerell report symptomatology caused by the suppression of surrounding anatomical structures. This symptomatology represents a wide range of symptoms that can be manifested in different age groups. Very early childhood symptomatology is caused by the esophageal and tracheal suppression, which is due to the vascular ring rather than the diverticulum itself. In late childhood or adult symptomatology, symptoms are most commonly caused by diverticulum dilatation. On the other hand, diverticulum wall dissection or spontaneous rupture occurs in 19% to 44% of cases. The papers suggest that the degeneration of diverticulum wall media leads to its dilatation and surgical intervention should be indicated at its growth [5, 11]. Ikeno et al. recommend surgical intervention in asymptomatic patients already at diverticulum of 50mm [5]. On the other hand, there are currently no clear indication criteria and recommended procedures for the therapy of this nozological unit [5].

Several options are currently described when indicating an operation. In childhood, many authors use the possibility of diverticulum exclusion without reconstructing the subclavian artery, which is very well tolerated in childhood. On the other hand, such performance in adult patients must be considered as suboptimal and not recommended [5]. In adult patients, some authors prefer to replace a portion of the descending aorta by sewing the aberrant subclavian artery at this site [5]. Other authors prefer to replace the descending aorta and to bridge the subclavian artery with bypass [12]. Thus, revascularization can be performed in

situ, or by connecting the arteria subclavia with the ipsilateral arteria carotis communis [10, 12]. In situ restoration brings two advantages - a complex one-step solution and avoidance of bypass surgery on the neck with the risk of sudden vascular accident and laryngeus reccurens nerve and phrenicus nerve injury. Further, we cannot omit to mention the risk of later bypass thrombosis. The disadvantage of in situ reconstruction is then the length of the formed subclavian artery [13]. Nevertheless, it is favored by most authors [5]. Other authors prefer as indicated performance the replacement of the entire aortic arch and part of the descending aorta [14]. The development of endovascular medicine has also been successful in the treatment of this anatomical modality [15]. In view of the many alternatives and confusion in the recommendations for the treatment of diverticulum of Kommerell, we can conclude that there is no ideal therapeutic approach, and each operating variant carries specific risks.

The results of the operation are relatively satisfactory, both after in-situ reconstruction of the subclavian artery and after the extraanatomical solution. Tanaka et al. reported an early mortality rate of only 11% for an almost 95% acute performances [10]. In endovascular intervention, the 1-year mortality rate is 2.6% [10]. Although some authors condemn this method because of the absence of aneurysm volume reduction and endoleak risk, which does not ensure the withdrawal of symptomatology, which is mainly due to the suppression of surrounding structures, long-term results are not available at the time of this publication.

Patent Ductus Arteriosus

The patent ductus arteriosus is the persistence of the open link between the aorta and the pulmonary truncus. Ductus is required for intrauterine fetal circulation and should be spontaneously closed on days 2 to 3 after birth. Its persistence leads to overload of pulmonary circulation on the one hand and systemic hypoperfusion on the other. The major risk factors for this congenital malformation are delivery before gestational week 28, excessive infusion therapy, respiratory insufficiency, sepsis, phototherapy, and application of furosemide [16, 17]. On the other hand, the open ductus arteriosus leads to bronchopulmonary dysplasia, necrotizing enterocolitis, renal insufficiency, diastolic heart failure, lagging neurological development and retinopathy in the neonate. It may also be a direct cause of neonatal mortality [16, 18]. In the field of severe pulmonary hypertension, or other complex congenital heart defects, the persistent ductus arteriosus allows the maintenance of systemic circulation by a short circuit from the truncus pulmonalis to the aorta. On the other hand, in its isolated occurrence, the short circuit is the opposite thus overloading the pulmonary circulation [16]. Prior to the echocardiography era, diagnosis of the patent ductus arteriosus was based on the presence of cardiomegaly in the x-ray image, edema of the lung and murmur. The first surgical therapy for this defect was made in 1938. In 1972, Elliot and Starling first pointed out the role of prostaglandin in the development of this defect. Since 1976, chloroquine has been used as a prostaglandin antagonist and since 1977 indomethacin [16].

Whether a child is born in time or prematurely, closure of the ductus arteriosus may be delayed or fail completely. However, the risk at premature births increases significantly. The persistent ductus arteriosus can be defined as pathological after the third day after delivery [16, 17]. The persistence of the open ductus arteriosus immediately after delivery in the absence of other congenital developmental disorders will cause reversion of the flow from the aorta to the pulmonary truncus. Thus, the pulmonary circulation is temporarily volume

overloaded and the systemic circulation is hypovolemic, which is called "ductal steal". During intrauterine development, the ductus arteriosus remains open due to prostaglandin receptors. On the one hand, the expression of receptors for these substances is higher at this stage of development, and their systemic circulation is higher [19, 20]. Oxygen acts on the ductus arteriosus as a constrictor. Hemodynamically, the ductus arteriosus is also variable. The shorter length of the ductus arteriosus leads to its higher flow. This is also increased by the higher systemic vascular resistance and, on the other hand, by the decrease in pulmonary resistance. Further, the flow is increased by prostaglandins and lower blood viscosity [16].

Late diagnosis of persistent ductus arteriosus has significant clinical consequences and therefore the significance of this shortening must be properly diagnosed. The most common symptomatology includes cardiovascular, renal, respiratory and gastrointestinal consequences of this congenital malformation. The most characteristic cardiovascular symptoms include wide pulse wave, hypertension, and audible murmur. The turbulent flow of blood in the ductus arteriosus produces a typical murmur for this diagnosis. In addition, the volume overload of the pulmonary artery also overloads the left compartments of the heart. The decrease in systemic perfusion is particularly marked during diastole, which significantly affects the myocardium, due to its dependence on circulation during this phase of heart rhythm [21]. Further, circulatory changes by hypoperfusion manifest themselves on the kidneys by fluid retention, metabolic acidosis, and oliguria. Laboratory parameters suggest hyponatremia and elevated creatinine concentrations. Ultrasound examination can confirm the zero and even reverse flow of the renal arteries in diastole [16]. Hypoperfusion activates the renin-angiotensin-aldosterone pathway with subsequent reuptake of sodium and water. Supranormal pulmonary circulation with volume overload results in pulmonary edema, the need for assisted ventilation, pulmonary bleeding, and bronchopulmonary dysplasia [16, 17]. Volume overload reduces pulmonary resistance, which in turn increases the volume of blood flowing through the ductus arteriosus. Surfactant deficiency in premature infants only increases the risk of pulmonary edema [16]. Systemic hypotension and reverse flow during diastole also cause gastrointestinal hypoperfusion.

Suspicion of patent ductus arteriosus can be assumed in the accumulation of several symptoms, including clinical status, laboratory parameters and specific X-ray findings. However, echocardiography is necessary to unequivocally confirm or disprove the diagnosis itself. The newborn is characterized by the presence of dyspnea, a wide pulse, hypertension, malnutrition and rejection of food intake and, last but not least, a holosystolic murmur. Laboratory examination points to acidosis and elevation of inflammatory markers, especially C-reactive protein [19]. Subsequently, there is an elevation of the B-type natriuretic peptide and troponin T. The X-ray of the chest documents cardiomegaly and pulmonary congestion. However, a similar set of traits may also be present in neonates with other congenital developmental defects. Echocardiography is the gold standard in screening methods for both anatomy and pathophysiology of persistent ductus arteriosus. Thus, we have available parameters such as diameter of ductus arteriosus and its hemodynamics, as well as hemodynamic parameters of the left atrium and ventricle, as well as peripheral circulation, especially in the renal artery. The diameter of ductus arteriosus greater than 1.5 mm measured at the first 31 hours after delivery in neonates born before 29th week is the best early predictor of the patent ductus arteriosus with a sensitivity of 83% and a specificity of 90% [22]. Other evaluated parameters are the flow through the ductus arteriosus, the size of the left atrium, filling left atrial pressures, and the presence of reverse flow in the middle cerebral or

upper mesenteric artery [23]. An important marker is the pulsatile flow through the ductus arteriosus, which demonstrates the high quantity of short circuit and balancing the pressures in aorta and pulmonary truncus at the end of the diastole. The high filling pressures of the left atrium also confirm the volume overload of both the pulmonary circulation and the left heart components. The absence of end-diastolic flow or the presence of reverse flow in the middle cerebral or upper mesenteric artery already document a negative effect on peripheral circulation [16, 23].

Therapy of patent ductus arteriosus leads to its closure or minimization of effects on circulation. The therapy is divided into conservative, pharmacological, surgical and endovascular. Conservative therapy involves reducing left ventricular preload and improving gas exchange in the overloaded pulmonary bed. Furosemide, on the one hand, optimizes circulation, on the other hand, negatively affects the physiological closure of the duct, while its application leads to elevation of prostaglandin concentrations with an additional adverse effect. An invasive or non-invasive respiratory regimen with a positive end-expiratory pressure of 5 cm water column is suitable. Respiration optimization also has a protective effect on the left ventricle of the heart. Another point is an increase in hematocrit over 35% to 40% in order to increase blood viscosity and reduce flow through the ductus arteriosus [24]. Pharmacotherapy has been a key point in the therapy of its patency since the discovery of the role of prostaglandin in maintaining the ductus arteriosus. Prostaglandin inhibitors lead to natural ductus arteriosus constriction. Mainly non-selective inhibitors including indomethacin, ibuprofen and acetaminophen are used. Important is the management of other drugs and their interactions, in particular the association with gentamicin due to nephrotoxicity and glucocorticoids due to the risk of perforation of gastrointestinal tract [16, 25]. Failure of pharmacotherapy is an indication of surgical or endovascular intervention [16]. The oldest therapy for the patent ductus arteriosus is surgical ligation. The surgery is performed via the left-sided thoracotomy with the application of a vascular clip. A change in hemodynamic ratios leads to immediate changes in circulation hemodynamics, yet it is burdened by a wide range of complications including bronchopulmonary dysplasia, chylothorax and cardiopulmonary failure [16, 17, 19]. Intervention literature does not indicate any contraindications. The method of transvenous occlusion of the ductus arteriosus is currently being introduced [26]. A paper presenting percutaneous intervention in neonates weighing less than 2 kilograms is published. The paper presents earlier pulmonary rehabilitation after percutaneous intervention compared to a surgical open approach [27]. Dislocation of the device to the pulmonary bed is reported as a possible complication.

The last question remains the correct timing of therapy and possible intervention in these patients. In general, treatment should be initiated within 12 hours of delivery or at the first signs of hemodynamic instability. Prophylactic therapy with indomethacin should be indicated within 12 hours of delivery at preterm labor or very low birth weight. Studies show that timely application of indomethacin reduces the risk of intracerebral bleeding and the need for surgical intervention for patent ductus arteriosus [16, 17, 19]. On the other hand, indomethacin does not reduce the incidence of chronic pulmonary disease or neurological outcomes [28]. Conrad et al. in their review work state, that the prophylactic application of indomethacin is not indicated [16]. However, early screening of the patent ductus arteriosus is recommended so that a possible targeted therapy can be initiated even before the first clinical manifestation of the hemodynamic consequences of the short circuit. Early therapy leads to both a reduction in the incidence of complications and a generally higher success rate of

pharmacological treatment itself and a reduction in the need for surgical intervention [29]. Recent studies have documented a decrease in the frequency of indications for both pharmacological and interventional therapies, leading to a gradual tightening of their indication criteria [30, 31].

Aortic Coarctation

Aortic coarctation represents 5 to 8% of all congenital heart defects and affects about 0.4% of live births (Figure 2) [32]. It may occur on its own but is often associated with other congenital heart developmental disorders. In half of the cases it is associated with developmental aortic valve defects, most commonly with bicuspid aortic valve. Other common comorbidities include aortic arch hypoplasia, subaortic stenosis, mitral valve abnormalities, patent ductus arteriosus, and inter-chamber and inter-atrial septal defects [33-35]. Coarctation is defined as the sequential narrowing of the aortic lumen, caused by the thickening of the medial layer of the aortic wall [33, 36]. Its occurrence is also associated with aortic arteriopathy, especially near coarctation itself. It is localized most often on the opposite side of the aorta to the ductus arteriosus entry site but it may be located also above or below this level [33, 35]. Etiopathogenesis has not been definitively elucidated, and there are currently three theories of the origin of this congenital developmental defect pointing to three different time windows of its origin. Some authors point to abnormal embryonic development. Another group of authors presents a reduced intrauterine flow through this area of the aorta followed by regression. Finally, it is the excess tissue of the ductus arteriosus found in the wall of the descending aorta, which causes its narrowing early in the postnatal period [37]. Further multiple genetic mutations and syndromes are associated with aortic coarctation. First, it is Turner syndrome, then DiGeorg syndrome and Noonan's syndrome [33].

Figure 2. Aortic coarctation with most commonly localization and ductus arteriosus.

Prenatal diagnostics reduces early postnatal morbidity and mortality and reduces the costly and risky transfer of newborns to cardio centers with the possibility of preparing a pregnant woman. Prenatal ultrasound screening is the underlying diagnostic method for these diseases. Prenatal heart diagnosis should include four ultrasound sections of the heart, a three-chamber, four-chamber view, and an examination of left and right ventricular outflow tract [38]. However, we must say that despite the rapid progress in this diagnostic method, prenatal diagnosis of aortic coarctation is complicated. Therefore, many scoring systems are being used to at least partially objectify this diagnosis. Here we include the z-score of the aortic arch, isthmus/ductal score and score of pulmonary artery/aorta [33].

Despite prenatal diagnostics, the number of patients diagnosed is also early postnatal. Upon closure of the ductus arteriosus, aortic obstruction occurs with hypoperfusion of the lower body, including the kidneys. Abdominal hypoperfusion leads to metabolic disruption. In addition, congestion of the left heart can lead to its failure. Non-closure of the ductus arteriosus may partially supplement blood flow to the lower half of the body and ease symptomatology [33, 36]. Classical aortic coarctation symptomatology includes delayed, attenuated, or completely absent pulsation to the femoral artery, differential pressure in the upper and lower extremities greater than 20mmHg, and systolic murmur [33]. Comorbidity in the sense of aberrant subclavian artery or aortic arch hypoplasia may cause uneven pressures on the right and the left upper extremities and disturb the diagnosis of coarctation when comparing pressures on the specific upper and lower extremities. Aberrant subclavian artery is present in about 3 to 4% of aortic coarctation patients [39]. Newborns with symptomatic coarctation are indicated for the administration of prostaglandin E1 in order not to close the ductus arteriosus and to reduce symptomatology to the time of surgery. In the case of subclinical symptomatology, only patient monitoring is indicated. Surgery or intervention should be indicated early in order to prevent left ventricular hypertrophy due to increased afterload and subsequent heart failure [40, 41]. In late diagnosis, hypertension, intracranial aneurysms with risk of bleeding, left ventricular hypertrophy with congestive heart failure and suprastenotic dilatation of the aorta occur [35, 37].

Although X-ray is not the first-choice diagnostic method, the visible shadow of the pre-stenosis or post-stenosis aortic dilatation and the fourth-rib shadowing caused by the dilatation of the intercostal artery as collateral circulation may lead to considering the diagnosis of coarctation [35]. Ultrasonography has a much greater value in diagnosis with the possibility of a more accurate representation of the stenotic part of the aorta as well as the quantification of pressure gradients [33, 35]. Due to the location, transesophageal examination is even more accurate. Ultrasonography may also indicate possible comorbidities and left ventricular status [33]. Computed tomography provides advantageous morphological assessment of both the stenosis itself and the surrounding structures. However, the radiation burden largely limits repeated monitoring, especially of pediatric patients. Other negatives are the nephrotoxic effect of the contrast agent, as well as the inability to dynamically evaluate the pressure ratios. The elimination of radiation exposure thus prefers the use of magnetic resonance, especially when it comes to repeating the examination in patient monitoring. The use of gadolinium further enhances both the aortic and the collateral circulation imaging [42]. Contrast medium flow analysis may further evaluate stenosis pressure gradients and collateral circulation [42, 43]. Newer magnetic resonance methods also allow quantification of aortic wall stress and recalculation of collateral circulation capacity [44]. However, the examination needs to eliminate patient movement, which is very limited in children. On the other hand,

modern examinations include invasive catheter angiography, as the gold standard for aortic coarctation, allowing accurate representation of both the stenosis itself and the collateral circulation [35].

The non-treatment of hemodynamically significant coarctation leads to significant shortening of life by complications such as: congestive heart failure, endocarditis, aortic rupture, or stroke [33, 35]. In particular, the severity of stenosis and the presence of other congenital co-morbidities affect survival itself. Even in the absence of pressure differences between the upper and the lower half of the body caused by the developed collateral circulation, hemodynamically significant coarctation is indicated for surgical correction [33]. The aim of the correction is to reduce the aortic gradient and reduce hypertension. Proper timing of intervention is critical. Early intervention carries the risk of restenosis with the necessary reintervention, while later surgery the risk of developing hypertension and developing aneurysms [33, 36].

Figure 3. Subclavian- flap aortoplasty of aortic coarctation.

In neonates and young children, surgical intervention is the method of choice. Child age and anatomical conditions lead to the choice of one of several applicable surgical procedures. For mild stenosis, the preferred option is end-to-end anastomosis resection with approach from left thoracotomy [45]. In older children with prolonged stenosis, the most popular method is aortoplasty with a patch from the subclavian artery, but it brings with itself a higher risk of restenosis (Figure 3) [37]. In adults, when it is not necessary to think about the further growth of an individual, the first-choice method is resection with implantation of interposition [37]. Extraanatomic bypass is the method of choice in adults with a large network of collateral circulation. In the perioperative period, the patient is particularly at risk of paradoxical hypertension, complications of laryngeus recurrens nerve injury and subclaval steal phenomenon. Rare, but described, is a spinal cord injury with paraplegia [33, 37, 46].

Balloon angioplasty, as another therapy option, can be done in three to six-month old toddlers. Earlier intervention is not possible for the still active ductus arteriosus tissue. In general, it is a palliative technique in high-risk patients which is able to delay the definitive

solution after stabilizing the condition and improving the patient's fitness [33]. Dilation causes multiple ruptures of the intimal aortic layer followed by wall rearrangement, which on the one hand delays the risk of restenosis, but on the other hand increases the risk of wall dissection and rupture [39]. The risk of restenosis after this performance increases with decreasing age at the time of intervention. Stent implantation after dilatation increases the long-term stability of this therapy, reduces the risk of restenosis as well as aneurysm formation. The method is preferred in adults. Its application in children brings about the necessity of redilatation at the aortic growth as well as more frequent restenosis in intima hypertrophy. The future offers growing and biodegradable stents, but they do not yet have long-term results [33].

Therapy results are controversial. A quarter of patients undergo cardiovascular intervention [47]. Recoarctation is found in 4-14% of patients. The higher incidence is in patients less than one year old [33]. Further, reinterventions are needed more frequently after balloon angioplasty with or without stent implantation compared to surgical intervention. Due to the high coincidence of coarctation and bicuspid aortic valve, aortic regurgitation or stenosis in hemodynamic borderline recoarctation is a frequent indication for surgery [33, 34]. Further, the aortic wall prior to coarctation exhibits reduced levels of smooth muscle cells and increased collagen levels, which affects local hemodynamics and increases the incidence of prestenotic dilatation. The incidence of aneurysm is 13% in patients after correction of coarctation, with a higher proportion of patients with plasty by help of patch [47]. Hypertension as an additional complication has an incidence of 35-68%, with a higher proportion of patients who have undergone coarctation correction at a later age. The exact etiology of hypertension formation after correction of coarctation is unclear and the hypotheses point to abnormal baroreceptor function, specific aortic arch geometry, persistent subclinical stenosis at the coarctation site, and renin-angiotensin-aldosterone system disorder [33]. Left ventricular hypertrophy at the time of coarctation may lead to late myocardial fibrosis with subsequent heart failure. In particular, the subendocardial fibrosis present demonstrates insufficient flow through the coronary artery with insufficient diastolic perfusion. The risk of ventricular failure with later coarctation intervention increases [33, 36].

Pseudocoarctation

Pseudocoarctation is a much more rare diagnosis than coarctation. It is characterized by a kind of cranking of the descending aorta at the site of the ductus arteriosus. Unlike coarctation, neither the pressure gradient nor the collateral circulation is present. The embryological nature is the pathological fusion of the dorsal aorta and the fourth primitive aortic arch. The result is a pathological extension of the descending aorta. The unit is mostly asymptomatic without the need for correction performance. An indication for surgery is then rare symptomatology or aortic aneurysm formation in this site. The etiology of aneurysm formation in this diagnosis is the turbulent blood flow in the elongated aorta [4, 33].

Aneurysm of Descending Aorta

Aneurysm of the descending aorta represents aortic affection distal to the left subclavian artery. If the disease is limited cranially from the diaphragm, we call it the descending

thoracic aortic aneurysm (DTAA). If the disease crosses the diaphragm and affects also the abdominal aorta, we call it thoracoabdominal aortic aneurysm (TAAA). The view of the etiological agent of this diagnosis has changed. In the early twentieth century, the disease was most often the result of tertiary syphilis. Later and up to now, the etiology of aneurysm development has been due to aortic wall media degeneration, discussed in a later chapter, atherosclerosis, connective tissue disease, aortitis, coarctation, infection and trauma [48].

At the time of diagnosis, the majority of patients are asymptomatic, and the diagnosis is determined as a random imaging finding. Up to almost 50% of patients with this diagnosis may be asymptomatic, with symptomatology triggered by a process of aortic wall rupture or dissection [49]. Of the 57% of symptomatic patients, rupture is symptomatic in up to 9%. The most typical symptom is back pain between the shoulder blades. In the case of dilatation of the part of the aorta crossing the diaphragm, the disease may appear as an abdominal pain in the epigastrium. Less typical symptomatology resulting from the suppression of surrounding structures is hoarseness, cough, hemoptysis, dysphagia, and gastrointestinal obstruction or bleeding [48]. The more severe symptomatology then comes from the suppression of the vagus nerve and the laryngeus reccurens nerve. The mycotic form is often associated with erosion of adjacent vertebrae. Computerized tomography and magnetic resonance imaging are recommended as the first-choice imaging method for suspected diagnosis. The addition of contrast medium to examination may also reveal the presence of intraluminal thrombus, dissection, intramural hematoma, retroperitoneal hematoma, rupture and periaortal fibrosis, indicating inflammatory etiology of the disease [48]. Today, rarely used aortography is used as a method of choice.

In asymptomatic patients, the anatomical dimensions of the aorta are indicative of therapy. An aortic diameter of more than 5 to 6 cm, or an increase in diameter of more than 1 cm per year, presents a risk of rupture with indication of elective surgery [48]. In patients with connective tissue disease, such as Marfan syndrome, the aneurysm is indicated for surgery at earlier stages, i.e., with a smaller anatomical diameter. If the anatomical condition of the indication of surgery is not met, strict conservative therapy of hypertension and control at least once a year is indicated. In the case of symptomatic patients, it is not essential to fulfill the anatomical indication. As therapy, both endovascular percutaneous intervention and open surgery are contemplated.

In selecting endovascular or surgical therapy, it is the most important to evaluate the anatomical characteristics of aneurysm and physiological reserve of the patient [50]. The open surgical method shows good results and benefits in the long run, but it is more burdensome for the patient. Endovascular therapy is an alternative, especially for patients with cardiac and renal comorbidities, as well as patients after surgery at this site, or at very old age. The endovascular method compared to surgery is characterized by lower periprocedural morbidity and mortality [51-53]. On the other hand, a narrow landing zone, excessive aneurysm angulation, significant intraluminal thrombus, or significant calcification of the aneurysm wall significantly disadvantage and endanger the successful outcome of endovascular intervention. As a method of choice in at-risk patients with a narrow landing zone, hybrid performance is appropriate, when debranching of the aortic arch creates enough room for subsequent endovascular intervention [54]. Other methods such as elephant trunk are listed in the chapter on aortic arch. In case of caudal progression of the disease, the possibility of debranching the abdominal visceral branches of the aorta is also possible [55-57].

Current View of Etiology of Thoracic Aortic Aneurysm

Hypertension is the most important risk factor for thoracic aortic disease [58-60]. All factors that increase the pulsatile tension of the aortic wall then also act as risk factors for these diseases. Genetic predisposition is the second most important risk factor. In 20% of patients diagnosed with thoracic aortic aneurysm, a genetic mutation related to this disease has been proved [60, 61]. Renard et al. identify more than 15 genes whose mutation can affect the risk of aneurysmal aortic wall changes [62]. A bicuspid aortic valve is the most associated with these diseases from congenital heart abnormalities. Further, an association with a higher age and a higher incidence in men are known [60]. On the other hand, some studies document diabetes mellitus as a protective risk factor [63-65]. Further, a large proportion of patients with a positive family history and proven disease has no established etiological genetic predisposition [61]. In contrast, Marfan syndrome is one of the consistently studied etiological conditions of the disease based on the Fas Binding Factor 1 (FBN1) mutation leading to the disbalance of fibrillin-1 followed by aneurysm, or directly by aortic dissection [66, 67]. Aneurysmal changes in the aorta are caused by changes in the medial layer of its wall, which contains more than fifty interrelated microstructures of elastic fibers and smooth muscle [60]. Association of aneurysm formation with impaired smooth muscle function and reduction of total number of smooth muscle cells is expected, resulting in insufficient resistance to pressure loading. Further, a change in the extracellular matrix is described in terms of reducing the proportion of elastic fibers with accumulation of proteoglycans and collagen [60, 68, 69]. Similar changes, but to a lesser extent, can also be observed in healthy individuals depending on age.

We currently know two mouse experimental models of aortic disease in Marfan syndrome. The first is *Fbn1* *mgR/mgR*, which grows to the dissection stage within 8 months and *Fbn1* *C1039/+* where the aneurysm develops without progression to the dissection stage [70, 71]. Initial works have suggested an increased level of transformation growth factor- β (TGF- β) in these experimental models, leading to the application of losartan as an angiotensin II antagonist - type I receptor (At1r) to disrupt this pathological pathway in patients with Marfan syndrome. However, clinical studies have not confirmed the benefits of losartan, which would replace the use of β -blockers [72, 73]. However, the role of TGF- β remains important, as evidenced by genetic mutations directly affecting its transcription and also affecting the formation of aortic aneurysms [74].

The TGF- β family is involved in pathophysiological pathways affecting a wide range of mechanisms, including the modulation of smooth muscle cells, as well as the production and remodeling of the extracellular matrix [75-77]. Factors trigger their responses through receptors and Smad 2/3 binding: Smad4, as well as through non-Smad pathway supported by mitogen-activated protein kinases (MAPKs), which can also transfer angiotensin II stimuli [60]. Experimental works directly demonstrate that the administration of losartan causes At1r blockade and leads to the prevention of aneurysm in experimental animals. Thus, the authors suggested that the overproduction of TGF- β due to At1r stimulation was responsible for aneurysm in patients with Marfan syndrome [70]. Increased TGF- β activity has also been reported for mutations that do not directly affect its transcription, including fibulin-4, α -actin specific for smooth muscle and myosin heavy chain [78-80]. The heterozygous forms of mutation of intermediates involved in this pathophysiological pathway also affect change of TGF- β production [60]. Thus, TGF- β is involved in multiple points and multiple mechanisms

in the pathogenesis of aortic aneurysm, which makes it not easy to use as a therapeutic point of action. Thus, new studies using genetically modified mice have denied the original works that put TGF- β at the center of the pathomechanism between Marfan syndrome and aneurysm formation. Blocking TGF- β at an early postnatal period in Fbn1 mgR/mgR mice accelerated rather than prevented aortic dissection [81]. Further studies have confirmed the negative effect of genetic inhibition of TGF- β by the Tgfbr2 gene on the development of dissection in this experimental model [82-84]. Further, elevated levels of Smad2 and Erk1/2 in the aneurismatically altered aortic wall of Fbn1 C1039/+ mice [85] have not been confirmed. The development of aneurysmatic aortic dilatation in blocking Tgfbr2 in healthy mice reintroduces the pathophysiological pathway of TGF- β into the etiopathogenesis of aortic aneurysm formation [82, 83]. Further, inactivation of Tghbr2 will cause smooth muscle cell disruption, decreased insulin-like growth factor 1 (IGF1) production, and impaired mechanical strength of binding of media and adventitia in the aortic wall [83]. Reflecting the protective influence of affecting the pathophysiological pathway of TGF- β on the development of aneurysm in patients with Marfan syndrome and genetically non-knockout mice, the application of drugs targeted at this pathomechanism, especially in childhood, could prevent or at least slow down the development of aortic aneurysm in children with Marfan syndrome [86]. The controversial effect of the disruption of the TGF- β pathway by its genetic blockade and medical affecting at Fbn1 C1039/+ mice remains a fact [83]. Further, due to the fact that neutralization of TGF- β leads to the progression of aneurysm formation and the application of losartan has a protective effect in Fbn1 mgR/mgR mice, the theory that TGF- β is an unequivocal mediator of At1r hyperactivity in accelerating the formation of aneurysm is refuted [81]. The role of TGF- β in the later formation of aneurysm in Fbn1 mgR/mgR mice was confirmed by prolonged survival and its later development when TGF- β neutralizing agents were applied early after termination of vascular embryogenesis [81]. Thus, by the summary of the results of controversial studies we find a parallel in the effect of TGF- β as a suppressor of early tumor growth and, on the other hand, a promoter of metastatic dissemination at its later stage [60].

Despite the controversies discussed above, it is now generally accepted that the angiotensin II pathway is significantly involved in the progression of both thoracic and abdominal aneurysms of the aorta [87, 88]. The angiotensin II pathway is upregulated by differential mechanisms in different experimental models of aortic aneurysm. The fact that genetic inactivation of At1ar in Fbn1 C1039/+ mice does not prevent the formation of aneurysm, has led to the theory that the protective effect of losartan rests on another than primary target receptor of this substance [89]. Given the inactivation of the effect of losartan by inhibiting NO synthase and the protective effect of endothelial NO synthase on the formation of aneurysm in Fbn1 C1039/+ mice, it has been hypothesized that the released endothelial NO can promote the effect of losartan [89, 90]. This includes endothelial cell dysfunction in the pathomechanisms of aneurysm formation as such. Despite the significant progress in the detection of aortic aneurysm pathomechanisms, we have only a limited possibility of slowing down its development in risk individuals. Surgical and/or interventional therapies continue to be therapies without a full-fledged alternative.

DISSECTION OF DESCENDING AORTA

Aortic dissection means a rupture of the intimal layer, with blood passing between the intima and the medium and forming a false lumen. Although the first mention of this diagnosis is very historic, the first anatomical description comes from the seventeenth and eighteenth centuries. From the same period comes also the Maunoir's term-dissection. The first therapeutic intervention then comes from the beginning of the twentieth century, when fenestration was created for hypoperfusion therapy [48]. In the mid-twentieth century, Abbott and Paulin developed a method of coating aorta with cellophane to prevent rupture. Albert Einstein was treated with a similar technique [48]. Surgical techniques for the treatment of this nosological unit have also improved with the development of extracorporeal circulation [91].

Aortic dissection classification is based on the site of its onset and localization of progression. The subtype is then subclassified on the basis of its origin. For an acute dissection is considered a dissection with onset less than 2 weeks ago. The term chronic is reserved for dissection of the aorta with time of onset more than 2 months ago. Subacute dissection refers to an intermediate stage with an onset time of more than 2 weeks and less than 2 months [48]. Two classifications are most commonly used today for anatomical definition. DeBakey classification divides aortic dissections based on disease localization and progression (Figure 4). This classification more precisely defines anatomical disability and is more suitable for comparison of individual therapeutic procedures in vascular surgery [48, 92]. Stanford classification is strictly functional based on the localization of the intimal rupture site.

Figure 4. DeBakey aortic dissection classification.

Aortic dissection is the most common lethal diagnosis affecting the aorta. The works document a three-fold higher incidence compared to abdominal aortic rupture [93]. The

worldwide incidence of this disease varies between 5 and 30 cases per million inhabitants per year. Lethal cases that fail to be diagnosed should be added to this incidence. Cohn et al. present a significantly more frequent occurrence of type A dissection compared to type B [48]. There are several hypotheses on the etiological cause of tear in the intimal layer, several of which are based on biochemical abnormalities in the medial layer of the aortic wall. However, the direct relationship between intimal rupture and media necrosis has not been explained. In addition, media degeneration is described only in a minority of patients with dissection, particularly in children [94]. Another theory describes hemorrhage in the aorta wall from vasa vasorum that weakens the intima and conditions its rupture. However, intramural hematoma is found only in less than a quarter of patients with dissection [95]. Another group of authors points to the penetration of atherosclerotic ulcer with subsequent spread to the environment, justifying the same indication criteria for the therapy of penetrated atherosclerotic ulcer as aortic dissection [96]. Despite the ambiguity of the etiopathological origin of the dissection, several risk factors have been identified, including arterial hypertension, Ehler-Danlos syndrome, Marfan syndrome, Turner syndrome, Sheehan syndrome, Cushing syndrome, cystic aortic disease, aortitis, iatrogenic aortic wall damage, bicuspid aortic valve, trauma, aortic coarctation, congenital aortic stenosis, polycystic kidney, pheochromocytoma and others [48]. In general, these are factors that increase the mechanical load on the aortic wall or reduce its mechanical strength. Hypertension is found in two thirds of patients with dissection [97]. Next, we will only deal with type B dissection, which falls into this chapter.

Type B aortic dissection represents about 40% of all aortic dissections and its course is less destructive compared to type A [48, 97]. More than half of the patients are able to heal a defect in conservative therapy, and only about 20-30% of patients undergo emergency surgery or intervention. Conditions requiring intervention include aortic rupture, aortic expansion, hemodynamic instability, persistent pain, hypertension unresponsive to treatment, and in particular peripheral tissue hypoperfusion [48, 97, 98]. The most common cause of death in this nosological unit is rupture of the aorta and hypoperfusion of the visceral organs [48]. In the case of sufficiency of conservative progression-free therapy, only 10% mortality during hospitalization can be expected [98]. During the first year, the survival rate drops to 85%, and in a 5-year follow-up, 29% overall mortality can be expected [99]. On the other hand, in patients indicated for surgical performance, the 30-day mortality rate is 30% [97]. These values have led to intensive introduction of endovascular methods that show mortality in the same group of patients at 5% [100]. In view of the results of invasive and conservative therapy, the indication of interventional or surgical therapy in aortic dissection type B is the sole risk of life-threatening complications [101, 102]. Thus, indications include persistent uncontrollable pain, medically untreatable hypertension, fast-growing aortic diameter, progression of the extent of dissection despite utilized conservative therapy, signs of development of rupture, or hypoperfusion in the catchment area of the affected aorta [48].

The goal of endovascular intervention, which is now the first choice in the treatment of type B aortic dissection, is to redirect the blood flow to the right lumen and to ensure tissue perfusion from the branch lines in the intervened site. Obliteration of the false lumen is desired, but not unconditional, however its thrombosis will, in the long run, provide stabilization of the aortic wall and limit the increase in aneurysm size. The stentgraft should cover and obture the primary intimal rupture, leading to thrombotization of the false lumen and reperfusion of the outgoing branches. If the reperfusion of the outgoing branches is

unsuccessful, the possibility of the intima festering at the site of separation is then possible, thereby transferring blood from the false to the right lumen of the aortic branch. Subsequently, the site may be covered with a stent [103]. If necessary, another stent can be implemented directly into the outgoing branch. With high intimal tear localization, stentgraft implantation can also cover the separation of subclavian artery of l.sin, except when the left arteria thoracica interna is used for myocardial revascularization, Willis circuit incompleteness, left vertebral artery domination, or vertebral artery occlusion. In these cases, performance is only feasible after its revascularization [104]. The need for higher stentgraft implantation requires debranching of the aortic arch, which is discussed in another chapter.

Open surgical intervention for dissecting a descending aorta is performed under general anesthesia with selective pulmonary ventilation. Monitoring of pressure via radial artery and femoral artery is necessary. A dreaded complication is the spinal cord injury leading to paraplegia occurring in one third of patients [48, 105, 106]. In order to protect the spinal cord, several protective measures are introduced, including cerebrospinal fluid drainage, perioperative bypass between left atrium and femoral artery and reimplantation of arteria intercostalis [107]. As the surgical approach, the left posterolateral thoracotomy is selected at the patient's right flank position. In the case of intervention in the abdominal aorta, we extend the incision and use a transperitoneal or retroperitoneal approach. In emergent operation, the strategy of the various workplaces is controversial. One group of authors recommends minimizing the surgical procedure to the part of the aorta most affected by dissection, rarely exceeding one-third of the thoracic descending aorta. Other workplaces, on the other hand, are expanding the performance on the whole aneurysmatically dilated aorta [48].

SURGERY PROCEDURES

One of the most important parts of the open surgical solution of the descending aortic aneurysm is the protection of peripheral tissues and organs, which we will deal with later. Schepens et al. describe the surgical procedure as follows [108]. The patient's position is on the right side with a 60-degree pelvic flexion and selective intubation to visualize the left pleura. The authors recommend continuous monitoring of ECG, arterial pressure, central venous pressure and pressure in the truncus pulmonalis. It is necessary to implant four venous catheters of sufficient diameter to allow rapid transfusion therapy. The authors recommend two cell-saver devices and continuous monitoring of patient diuresis. Further, continuous measurement of intrathecal pressure by a catheter implanted between the third and fourth lumbar vertebrae is also recommended, while the pressure should not exceed 10 mmHg. If all procedures are observed epidural cooling is not required according to the authors. If targeted hypothermia is not used, the patient is let spontaneously slowly cooled down to 32 degrees Celsius. When the aneurysm interferes with the aortic arch, the authors choose deep hypothermia. As an operative approach, the lateral thoracotomy in the sixth intercostal extended by diafragmatomy is selected. The abdominal aorta is visualized by retroperitoneal approach. Left atrial cannulation is performed via the upper or lower pulmonary vein, rarely via the left atrial ear. If the proximal part of the aorta is not affected, the authors do not rule out this cannulation site either. Blood is applied through the arterial line to the femoral artery (Figure 6). When the left ventricular bypass is triggered, we clamp the descending aorta

gradually in the cranio-caudal direction with the gradual sewing of all anastomoses. Further, the application of 300mL of cold crystalloid solution every 20 minutes to renal arteries is recommended. Schepens et al. do not recommend the selective application of blood from the left ventricular bypass to the visceral branches of the aorta. Patient warming may be either active or spontaneously slow during the stay in intensive care unit [108].

Organ Ischemic Injury Protection

The first option to protect peripheral tissues and organs is hypothermia [109]. The patient is linked to full extracorporeal circulation, most often via the peripheral cannulation of the arteria and vena femoralis. After the extracorporeal circulation is triggered, we start cooling the patient with an arterial temperature of 15 degrees Celsius. We use left-sided thoracotomy as the surgical approach. When ventricular fibrillation develops, a decompression suction catheter is placed through the tip into the left ventricle. When the temperature reaches 20 degrees Celsius, we stop the extracorporeal circulation, we clamp the descending aorta distally from the proximal suture site. The lower body is perfused 1 - 1.5 L/min while maintaining hypothermia. Subsequently, we perform a suture of proximal anastomosis. At anatomical availability other perfusion lines can be implanted into the left arteria carotis communis and truncus brachiocephalicus with a flow rate of 10mL/kg/min. After the end of proximal anastomosis, we start also the circulation of the upper half of the body by flowing 1 - 1.5 L/min. We perform suture of individual branches of the aorta in cranio-caudal direction with possible selective perfusion especially of visceral branches (0.2 - 0.3 L/min). Upon completion of the visceral branch suture, we can begin to warm the patient [109].

The Gott shunt represents the link between the aortic arch and the descending aorta below the surgical intervention site (Figure 5). Verdant uses a 9mm heparin coated prosthesis. To prevent undetected malfunctions of this method, the authors recommend applying a flow meter to the shunt. In the study was reported one case of failure resulting in spinal cord injury due to ischemia. The mean systolic pressure in the lower half of the body was 61 mmHg with optimal functionality of the method [110].

Left ventricular bypass represents a newer methodology compared to Gott shunt. Cannulated is the pulmonary vein and the blood is applied to the arterial system of the lower half of the body without a reservoir by a centrifugal pump (Figure 6). It is recommended to administer a partial dose of heparin with an activated clotting time (ACT) of 150 seconds. The authors recommend monitoring of radial and femoral pressure, cardiac output, venous saturation, central venous pressure and pressure in the truncus pulmonalis [110]. Verdant presents a 9mm Gott shunt 3L per minute in the treatment of the descending aortic traumatic injury, and a 4L per minute at use of controlled left ventricular bypass. Thus, the incidence of spinal cord injury during performance was eliminated from 3/40 patients at Gott shunt to 4/98 at left ventricular bypass [110].

Figure 5. Gott shunt.

Figure 6. Left heart bypass.

The use of partial cardiopulmonary bypass is another controlled form of lower body perfusion in the operation of the descending thoracic aorta (Figure 7). Its use is associated with a low incidence of ischemic damage to peripheral tissues, particularly spinal cord [111]. The venous line is most commonly introduced via the peripheral cannulation into the right atrium of the heart, from where the blood is drawn into the extracorporeal circulation. There it is subsequently oxygenated and applied to the arterial system of the lower half of the body, most commonly via the peripheral cannulation of the femoral artery. This ensures a fully controlled double circulation. Respiration and oxygenation of the upper half of the body is mostly ensured by selective intubation. The perfusionist by modification of the flow through the venous line modulates the preload of the heart and the cardiac output under invasive pressure monitoring, most commonly the radial artery or the brachial artery. The flow through the arterial cannula of the extracorporeal circulation itself then again ensures the perfusion of the lower half of the body. The method is also applicable at aberrant separation of the subclavian artery. Nakamura et al. present the use of this method in three patients with aortic coarctation with optimal outcome [112]. The method is a very suitable alternative for workplaces with experience in using cardiopulmonary bypass with peripheral cannulation. The disadvantage remains the need for full heparinization of the patient due to the use of the oxygenator.

Figure 7. Partial cardiopulmonary bypass (FA – femoral artery; FV – femoral vein).

Results and Benefits of Open and Endovascular Descending Aorta Therapy

Harky et al. in 2019 published a review and meta-analysis comparing endovascular and surgical treatment of aortic diseases [113]. A population of more than 14,000 patients points to a preference for open surgical approach in young patients, where the group of patients undergoing surgery was nearly 5 years younger. The group of patients undergoing endovascular therapy showed a higher coincidence of coronary heart disease, hypertension, and chronic renal failure. Despite the lack of definite indications and contraindications, endovascular therapy was mostly chosen in patients where an open surgical approach would be a high risk [113, 114]. Most patients in meta-analysis represented patients with degenerative aneurysms limited to descending aorta. Given the high proportion of this diagnosis in meta-analysis (99% in open surgery and 96% in endovascular treatment), most interventions were also conducted in an elective regimen (83% in open surgery and 81% in endovascular treatment) [113].

Cheng et al. in their meta-analysis involving more than 5.5 thousand patients, present higher mortality after open surgery compared to endovascular intervention over 30 days (OR = 2.27), one year (OR = 1.36) and 3 years (OR = 1.09). However, with a longer follow-up time, the difference was no longer significant [115]. Harky et al. present significantly higher mortality during hospitalization when using endovascular intervention, which may be partly due to higher age and more frequent comorbidities in this patient group. However, survival assessments after one and five years did not show a statistically significant difference. The authors conclude that the unambiguous conclusion of the evaluation of the benefits of better survival after one of these methods cannot be stated but given the more frequent comorbidities and similar survival of the patients, they assume a slightly better endovascular outcome compared to open surgery [113, 116]. More can be expected from studies with longer postoperative patient follow-up. Further works also focus on the risk of neurological complications after a single type of procedure, while Gopaldas et al. in a study involving more than 11.5 thousand patients, find a comparable risk of neurological complications after each approach [114]. Harky et al. find higher incidence of postoperative paraplegia (OR = 2.07, $p = 0.007$) in open surgical intervention [113]. However, various studies included in this meta-analysis used different methods of spinal protection. Better results of surgical open approach are found in the assessment of vascular postoperative or post-intervention complications [114, 115]. Other benefits of the endovascular approach are lower risk of cardiac and renal complications and shorter hospitalization ($p = 0.0004$). In view of the risk of complications and reintervention, the authors prefer an open surgical approach [113]. Further studies with longer-term follow-up will bring the most important differences.

TRAUMA OF DESCENDING AORTA

The most common reason for traumatic thoracic aortic involvement is road accidents. Currently, we have seen a long-term increase in the incidence of this disease. This was due to the increasing incidence of injuries themselves in the 20th century, followed by the increasing quality of emergent medicine in the 21st century [117]. Even today, there is still a high mortality rate for these patients, which in the past was 80% [117]. Today, about 38% of

patients survive primary trauma and 4% die on the way to hospital. Survival of 24 hours after injury remains at 20% [118, 119]. Chest injury is the second most common cause of death following head trauma in road accidents and accounts for about 15% of all injuries treated in emergency department worldwide [120].

The most common location of traumatic aortic injury is, due to anatomic fixation, isthmus. The mechanism of injury is deceleration associated with chest compression, resulting in torsion and retraction of the aortic wall tissue. Mokrade et al. explain the significantly lower incidence of ascending aortic trauma not by the absolute lower number of injuries but by the severity of the wall destruction in this site, which mostly leads to immediate death [117]. In addition to traffic accidents, thoracic aortic injuries arise during crushing, fall from height and deceleration injuries in sports activities [117-119].

Figure 8. Classification of traumatic injuries of the thoracic aorta (AA – aortic arch; DA – descending aorta; LSA – left subclavian artery).

The initial management of a patient with suspected thoracic aortic trauma depends both on the overall condition of the patient and the associated injuries. Although transesophageal echocardiography is the primary choice for the diagnosis of thoracic aortic injury, the first imaging examination is usually computerized tomography, which should be performed as soon as possible considering the patient's condition [120, 121]. Computer tomography allows both accurate diagnosis of aortic injury itself and the diagnosis of associated injuries to other organs. Magnetic resonance imaging (MRI) also offers an alternative, but the examination is not normally available in continuous operation, moreover the length of the examination may

cause unwanted delay in therapy. Further, angiography is not unconditional for diagnosis, but it precedes the endovascular intervention itself as standard [117].

Computer tomography examination is also aimed at determining the aortic injury class, which is an unconditional step in determining treatment strategy. Starnes et al. published a classification that divides injuries into two basic groups. The first group is findings without abnormality on the outer contour of the aorta, which includes grade I and II. The second group consists of findings with an abnormality of the outer contour of the aorta. This group includes grade III and IV [122]. This allows for a simple and rapid determination of the severity of the injury as well as its therapy strategy. The severity of the finding is further confirmed and enhanced by the presence of mediastinal hematoma, left-sided hemothorax, and the presence of pseudocoarctation [123]. Attention should be paid to the presence or absence of changes in the external contour of the aorta, since it significantly affects the choice of the next therapeutic procedure. To identify grade I and II, the authors recommend multiplanar reconstruction, which may be more complicated in axial sections. Accurate localization of damage is directly a prerequisite for successful possible endovascular intervention [124]. The therapeutic plan is then still influenced by coincidence of injury of brain, spinal cord, abdominal cavity, pelvis as well as other traumatic changes. However, the examination is burdened with false positivity especially for the presence of movement artifacts. Computerized tomography with ECG synchronization or transesophageal ultrasonography is indicated when diagnosis is ambiguous [117]. On the other hand, the trauma image can falsely imitate the diverticulum of the aortic wall at the site of the ductus arteriosus, the hematoma mediastinal caused by the injury of the venous system, or other extra aortic anatomical structure [117].

The presence of a traumatic change in the aortic wall is not necessarily an indication for surgical revision or percutaneous intervention, and some injuries can also be managed conservatively [123]. Grade I and II injuries can also be managed by conservative therapy with consistent patient monitoring. Conservative therapy is sufficient for more than half of these injuries, and only 5% show progression of the finding with necessary change in treatment strategy [125]. Grade III injuries require intervention, while a more optimal endovascular intervention with stentgraft implantation is often sufficient. Therapy should be indicated within 24 hours of injury. However, excessive delay in intervention increases the risk of rupture with possible fatal consequences for the patient. Grade III with signs of marked damage and grade IV should be treated emergently, immediately endovascularly, or surgically. Harris et al. define a lactate level $> 4\text{mmol/L}$, mediastinal hematoma $> 10\text{mm}$ and at least a 4-fold increase in aortic diameter at the trauma site compared to the undamaged portion as a rupture prognostic factor [125].

Even in the treatment of traumatic aortic injuries, the progression of interventional endovascular percutaneous techniques has been observed over the past two decades. Some studies present a 30-day mortality and a survival rate of two-year follow-up at 93.7% in a successful 2.1% procedure [126, 127]. Other works report a 4% mortality rate during the procedure. Total periprocedural mortality is also affected by associated injuries and reaches 16%. The risk of spinal cord injury with a neurological deficit is less than 1% in this intervention [128, 129].

Surgical treatment remains the method of choice as another possible alternative at contraindication or unavailability of intervention therapy. Verdant published a study involving 138 patients undergoing open surgery for traumatic thoracic aortic injury [110].

The authors present a hospitalization mortality rate of 5%, while during the evaluation the mortality was reduced from 7.5% using the Gott shunt to 4% when the left ventricular bypass method was introduced. In the last 68 patients, the authors present a mortality rate of 1.4% after the adoption of the methodology. The authors report a newly created paraplegia only in one case because of the unrecognized malfunction of Gott shunt. Four patients were paraplegic already before surgery. The length of the aortic clamp was 29.3 ± 13 minutes in the study [110]. The aim of the surgical intervention in the traumatic damage of the descending aorta is periprocedural sufficient tissue perfusion with prevention of spinal cord damage.

ABDOMINAL AORTA, ILIAC, AND SPLANCHNIC ARTERIES

Vladimir Sihotsky*, MD, PhD

Department of Vascular Surgery,
East Slovak Institute of Cardiovascular Diseases,
Medical Faculty of Safarik University, Kosice, Slovakia

ABSTRACT

Surgery of the abdominal aorta, iliac, and splanchnic arteries is mainly performed due to occlusive disease or aneurysms. Aortoiliac atherosclerosis, the most common reason for the occlusive process, clinically presents as intermittent claudication or more advanced critical limb ischemia (CLI). The diagnosis is based on computed tomographic angiography (CTA) or conventional arteriography of the abdominal aorta and its branches. The treatment is indicated in clinical cases of limited claudication or CLI. The therapy may be endovascular or surgical. The gold standard of surgical reconstructions in the aortoiliac atherosclerosis is aortobifemoral bypass.

Atherosclerosis of splanchnic arteries leads to mesenteric ischemia. The treatment can be either interventional, which is the method of first choice, or surgical. Open surgical reconstructions for the mesenteric ischemia are targeted mainly at the superior mesenteric artery and may be an antegrade bypass, from the suprarenal aorta, or the retrograde bypass, mostly from the common iliac arteries.

An abdominal aortic aneurysm (AAA) is dangerous due to the risk of rupture, which has total mortality rate of 75%. The diagnosis of ruptured abdominal aortic aneurysm is based on a quick ultrasound or CTA. The treatment may be either endovascular or surgical. Both methods are possible and have comparable outcomes. Prevention of rupture is the treatment of AAA in the asymptomatic stage. For therapy in the asymptomatic stage are indicated aneurysms over 5.5 cm in transverse diameter. The crucial imaging study for the diagnosis of AAA is CTA. The treatments may be similar to the ruptured aneurysms surgical or endovascular treatments. Endovascular aneurysmatic repair (EVAR) of AAA is less invasive but has worse long term durability compared to the open surgery. Thus, EVAR is indicated in patients with suitable aortic

anatomy and the elderly. Open surgery may be considered as a method of first choice in younger patients with longer life expectancy. Aneurysms of splanchnic arteries may lead to severe bleeding. This treatment is indicated for symptomatic aneurysms and those aneurysms which are over 2 cm in transverse diameter.

INTRODUCTION

Arterial reconstructions of the abdominal aorta, iliac, and splanchnic arteries are performed mainly due to aortoiliac atherosclerosis, as the obliterative disease and aortoiliac aneurysms. The first aortoiliac reconstruction was performed by Wylie in the U.S.A. In 1951, he made thrombendarterectomy of aortic bifurcation because of atherosclerotic obliteration [1]. The first reconstruction because of aortic aneurysm was done by Dubost in Paris in 1951 [2]. He reestablished the continuity after resection of a ruptured aortic aneurysm by a preserved human aortic graft. In 1954, De Backey and Cooley referred about six cases of ruptured aortic aneurysms to be also replaced by human aortic allografts [3].

However, further development of aortoiliac reconstruction was not possible because of the lack of human aortic allografts, which represented the only possibility of the restoration of the aortic flow. The situation was changed the invention of prosthetic grafts, constructed from Vinyon N by Vorhees in 1952 [4]. These grafts started to be widely used in the bridging of arterial defects and arterial reconstructions. The golden era of aortoiliac arterial reconstructions began with the invention of prosthetic grafts, and the aortobifemoral bypass started to become the “gold standard” of the surgical treatment of aortoiliac atherosclerosis [5]. The introduction of endovascular treatment of aortic pathologies was the second important factor that changed treatment possibilities. Gruntzig in 1974 was the first to do percutaneous transluminal angioplasty and started the modern era of endovascular treatment. At the beginning of the new millennium, the extensive development of interventional procedures changed approaches in the treatment of aortoiliac pathologies. Surgery is reserved only for patients with the most advanced disease. Aortoiliac reconstructions are performed as the surgical treatment of aortoiliac atherosclerosis that cannot be treated endovascularly, mainly TACS D patients, according to the TASC classification [6].

The surgical treatment of AAA is indicated for patients with an asymptomatic AAA with more than 5.5 cm in the transverse diameter or patients with ruptured aneurysms [7]. Endovascular treatment of asymptomatic or ruptured AAA should be indicated for patients with appropriate anatomy of AAA, but results of trials are conflicting and do not prefer a stentgraft placement [8, 9]. Arterial reconstructions at visceral branches of the abdominal aorta are not commonly performed. The primary indication of them is chronic visceral ischemia and visceral aneurysms.

AORTOILIAC OCCLUSIVE DISEASE: GENERAL CONSIDERATIONS

Etiology

The common reason of walking disability is chronic lower extremity ischemia. Typical symptoms include claudication and critical limb ischemia. These symptoms are caused by peripheral arterial disease (PAD), the disease which is characteristic for older patients. The United States National Health and Nutrition Examination Survey reported a 4.3% prevalence of PAD in the overall population, and 14.5% in patients more than 69 years old [10]. PAD is defined when an ankle-brachial index (ABI) is less than 0.9 even if the symptoms are not present [11]. The most common reason for PAD is aortoiliac and peripheral artery

atherosclerosis. The other causes are thromboangiitis obliterans, fibromuscular dysplasia, popliteal aneurysms, and entrapment syndrome are much less common [6].

The risk factors for peripheral artery atherosclerosis are male gender, smoking, diabetes, dyslipidemia, old age, hypertension, hyperhomocysteinemia, and renal insufficiency and are similar to the general atherosclerotic risk factors [12, 13, 14]. Thus, patients with PAD have cerebrovascular disease (CVD) and coronary artery disease (CAD) more often than the rest population [15].

Pathology

The main reason for aortoiliac occlusive disease is atherosclerosis and is often combined with infrainguinal atherosclerosis. The aortoiliac disease typically begins at the distal aorta and the common iliac artery origins and slowly progresses proximally and distally. Some theories are trying to explain why namely the distal aorta is confined by aortoiliac atherosclerosis. The explanation may be the fact that laminar blood flow changes to turbulent flow on the aortic bifurcation and continues distally along the common iliac arteries. The turbulent flow may increase shear stress at the endothelium and result in small ruptures that lead to the development of atherosclerosis. The disease slowly progresses and may lead to total aortic occlusion. Collateral circulation has time for development. The primary compensatory networks develop from the lumbar and hypogastric vessels and connect to circumflex iliac, hypogastric, femoral, and deep femoral arteries. In more advanced obstructions, collaterals include the internal mammary artery-to-inferior epigastric arteries and the superior mesenteric artery-to-inferior mesenteric artery and hemorrhoidal artery pathway. The latter collateral comprises the arc of Riordan and the inferior mesenteric artery. It is necessary to recognize the presence of such significant collaterals because it should be preserved during operation [16].

Brewster divides aortoiliac atherosclerosis into three types (Figure1) [16]:

Type I, the localized disease, is confined to the distal abdominal aorta and common iliac arteries.

Type II, the more widespread intra-abdominal disease, is present.

Type III, the pattern denotes multilevel disease with associated infrainguinal occlusive lesions.

The incidence of type I is about 10%. This type has developed a good collateral system; the distal arterial system is not involved by atherosclerosis and thus lead rarely to critical limb ischemia. This type is typical for younger individuals with less underlying disease and smokers. Type II occurs in about 25% and type III in about 65% of patients. These types are more typical for men. Patients with type II and type III are typically older and are much more likely to have underlying diseases such as hypertension, diabetes, and associated atherosclerotic disease of cerebral, coronary, and splanchnic arteries. Progression of the arterial occlusive process is also more likely in such patients than in patients with the more localized aortoiliac disease. For these reasons, most patients with type III have symptoms of more advanced ischemia, such as ischemic rest pain or ischemic tissue necrosis [16, 17].

Figure 1. Three types of Brewster's classification.

Clinical Manifestation

Patients with aortoiliac atherosclerosis and hemodynamic impairment may present with typical claudication of the calf alone or also with the involvement of the thigh, hip, or buttock. About 5% of patients with limb claudication proceed yearly to critical limb ischemia.

Critical limb ischemia (CLI) is a more advanced stage of aortoiliac atherosclerosis and is typical for more advanced atherosclerosis, also involving infrainguinal arteries (type II and type III of aortoiliac atherosclerosis). The CLI manifests as rest pain and ischemic ulceration or gangrene of the forefoot or toes, representing a reduction in distal tissue perfusion below resting metabolic requirements (Figure 2). The clinical diagnosis is objectively confirmed by hemodynamic measurements such as systolic ankle pressure less than 50 mm Hg and toe pressure less than 30 mm Hg [18].

There are two main widely used classification of arterial occlusive disease symptoms. The Fontaine classification is more used in Europe, while the Rutherford classification more used in the United States.

The Fontaine classification describes four stages of the arterial occlusive disease [19]:

Stage I – Asymptomatic

Stage I includes patients who are asymptomatic for most of the time, but in whom a thorough history may reveal non-specific, subtle symptoms, such as paresthesia. Physical examination may reveal cold extremities, reduced peripheral pulse, or murmurs in the peripheral arteries.

Stage II – Intermittent claudication. Patients often have a constant distance at which the pain appears:

Stage IIa – Intermittent claudication after more than 200 m of walking.

Stage IIb – Intermittent claudication after less than 200 m of walking.

Stage III – Rest pain. Rest pain appears mainly in the night when the legs are raised on to the bed, which decreases the gravitational effect present by day. Also during the night, the lack of sensory stimuli allows patients to concentrate on their legs.

Stage IV – Ischaemic ulcers or gangrene (which may be dry or wet).

The Rutherford classification describes seven stages of peripheral artery disease [20, 21]:

Stage 0 – Asymptomatic.

Stage 1 – Mild claudication.

Stage 2 – Moderate claudication – the distance that delineates mild, moderate, and severe claudication are not specified in the Rutherford classification, as it is in the Fontaine classification.

Stage 3 – Severe claudication.

Stage 4 – Rest pain.

Stage 5 – Ischemic ulceration not exceeding ulcers of the digits of the foot.

Stage 6 – Severe ischaemic ulcers or frank gangrene.

About 30% of male patients may have problems achieving an erection due to inadequate pelvic perfusion. Symptoms associated with terminal aortic occlusion are thigh, hip, or buttock claudication, atrophy of the leg muscles, impotence, and reduced femoral pulses are described as Leriche's syndrome.

Figure 2. Critical limb ischemia. CLI of the right lower limb, wet gangrene at the third and the fourth finger, stage IVb of Fontaine classification.

Diagnosis

The diagnosis of aortoiliac atherosclerosis can be made based on a history of claudication and absence of femoral pulses.

The ankle-brachial index (ABI) is determined by dividing the systolic pressure obtained by Doppler insonation at the ankle by the brachial arterial pressure. Usually, the ABI is 1.0, or a value below 0.90 which indicates occlusive disease. Any patient who has an ankle-brachial index (ABI) of less than 0.90 has significant PAD, even if the symptoms are absent.

Imaging Studies

Color duplex ultrasound can supply sufficient information to permit intervention in selected cases. Duplex ultrasound is considered the first line examination before more invasive methods like CT-angiography or conventional angiography.

CTA is useful for imaging the arterial tree (Figure 3). CTA has improved and is the dominant preoperative imaging modality for aortic aneurysm disease today, but infrainguinally, the caliber of the arteries and the presence of calcification in vessels, especially in diabetic patients, may limit the ability of computed tomographic angiography.

Magnetic resonance angiography (MRA) is continually improving and can be used to obtain images similar in quality to angiography in most cases. MRA does not show calcifications and gives a better visualization of crural vessels than CTA.

Figure 3. CT angiography, 3D reconstruction, of subrenal occlusion of the abdominal aorta due to aortoiliac atherosclerotic disease. The occlusion is marked by an arrow.

Figure 4. Arteriography (angiography), chronic occlusion of the distal abdominal aorta (marked by an arrow).

Conventional arteriography (angiography) provides detailed anatomic information about the aortoiliac and peripheral arterial disease, more precise compared to CTA or MRA. Aortoiliac surgery can be planned based on good-quality CTA or MRA, but conventional arteriography remains the “gold standard” of preoperative imaging before aortoiliac arterial reconstruction, especially for the patients with CLI and infrainguinal disease (Figure 4). The definitive distinction about the imaging study should be left on the operating surgeon [22].

Treatment

Nonoperative Treatment

Patients with claudication seek treatment for the relief of limiting pain. These patients exhibit a more benign form of atherosclerosis concerning limb viability, with amputation rates of 1% to 7% at five years. The natural history of untreated CLI is more dangerous and leads to limb loss more frequently than does claudication. Patients with CLI have a limb loss rate of about 25% in one year [6].

Nonoperative treatment is based on:

1. Reduction of cardiovascular risk factors – all patients should stop smoking. Reduction of elevated lipid levels. Statins are extremely useful in reducing LDL cholesterol
2. Exercise rehabilitation for claudicants – exercise ranging from unsupervised walking to regular supervised training on a treadmill significantly improves walking ability. During every session, the patient should be asked to walk until the limit of lower limb pain is reached, followed by a short period of rest till pain relief is achieved, then a return to exercise.
3. Pharmacotherapy – for aortoiliac occlusive disease represents the antiplatelet agents, aspirin, clopidogrel. Only pentoxifylline and cilostazol have achieved importance in the treatment of intermittent claudication. Pentoxifylline produces a modest improvement in walking distance, but some patients experience substantial long-term symptom relief with pentoxifylline, while others do not [5]. Cilostazol is a phosphodiesterase III inhibitor with a vasodilator, antiplatelet, and antilipid activity. Cilostazol also inhibits smooth muscle cell proliferation and platelet aggregation [5]. Cilostazol has shown increased maximal walking distances up to 50% and also significant improvements in health-related quality of life [5]. Despite the improving results of pharmacotherapy, remain endovascular and surgical revascularization, essential treatment modalities for patients with symptomatic aortoiliac atherosclerosis.

Indication for Invasive Treatment

Indication for arterial reconstructions in patients with the aortoiliac occlusive disease is disabling claudication or CLI. Disabling claudication is a relative indication and means the claudication that limits patients in everyday life. The annual rate of limb loss in patients with claudication is about 1% [22]. The indication for arterial reconstruction should take into account patients age, overall status, and underlying diseases. For example, for a 50-year-old

patient who is active, claudications after 200 m may be disabling, while for an older individual claudications after 50 meters may not represent limitations in everyday activities. The decision for endovascular or surgical treatment should be carefully and individually considered.

Endovascular Treatment

Approximately 70-80% of PAD patients indicated to invasive treatment are managed endovascularly, the rest of 20-30% patients are treated surgically. The decision of surgical or endovascular treatment is made according to TACS (Trans-Atlantic Inter-Society Consensus) criteria [6]. The TASC working group has classified anatomic patterns of disease involvement (types A through D) for the aortoiliac (Figure 5-8) segments, based on recommended treatment (endovascular versus open surgery). The TASC working group advocated endovascular treatment for TASC type A lesions and surgical treatment for TASC type D lesions. For TASC type B and C lesions, the authors concluded that there was insufficient evidence to recommend one modality over the other definitively [6].

TYPE A LESIONS (Figure 5) [6]

- Unilateral or bilateral stenoses of the common iliac artery
- Unilateral or bilateral single short (3 cm) stenosis of the external iliac artery (EIA)

Figure 5. Type A lesion of TASC Classification.

TYPE B LESIONS (Figure 6) [6]

- Short (3 cm) stenosis of the infrarenal aorta
- Unilateral common iliac artery (CIA) occlusion
- Single or multiple stenoses totaling 3–10 cm involving the EIA not extending into the common femoral artery (CFA)
- Unilateral EIA occlusion not involving the origins of internal iliac or CFA

Figure 6. Type B lesions of TASC Classification.

TYPE C LESIONS (Figure 7) [6]

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3–10 cm long not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlusion with or without the involvement of origins of internal iliac and/or CFA

Figure 7. Type C lesions of TASC Classification.

TYPE D LESIONS (Figure 8) [6]

- Infrarenal aortoiliac occlusion
- Diffuse atherosclerotic disease involving the aorta and both iliac arteries requiring treatment
- Diffuse multiple atherosclerotic stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusions of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

Figure 8. Type D lesions of TASC Classification.

Endovascular therapy consists of image-guided techniques to treat diseased arterial segments from within the lumen of the vessel. Access to the arterial system is established by the insertion of valved sheaths, usually percutaneously, often through the common femoral artery. Once the target lesion is accessed, therapeutic maneuvers, such as angioplasty, or devices, such as stents, can be delivered. In many arterial beds, endovascular therapy is more commonly utilized than open surgical treatment because of its minimally invasive nature and reduction of short-term morbidity and mortality. Percutaneous transluminal angioplasty, with or without placement of an intravascular stent, is often the treatment of choice when the

stenoses or even occlusions are relatively short and localized. Stents and stentgrafts are commonly used from the aortic bifurcation to the distal popliteal artery. For short stenotic segments in larger, more proximal vessels, the results of endovascular therapies are good with 1- year success rates of 85% in common iliac disease and 70% in external iliac disease. The success of endovascular treatment for lower extremity occlusive disease is inversely related to the complexity of the lesion.

Finally, the selection of the best method of revascularization for a patient with claudication is based on a balance between the risks of the specific intervention and the durability of improvement that can be expected from the intervention. Thus, the natural history of claudication is relatively benign; that balance usually does not favor open surgery. In contrast, its relatively low morbidity and mortality make endovascular therapy particularly attractive, and when it is anatomically feasible, endovascular treatment is generally preferred to open surgery for most cases of claudication. Usually, short stenoses and occlusions are treated endovascularly. However, the longer and multiple occlusions and lesions that cannot be treated interventionally are indicated for surgery.

AORTOILIAC OCCLUSIVE DISEASE: SURGICAL TREATMENT

Preoperative Management

Careful evaluation of the factors that influence operative risk and postoperative complications is an essential component of the surgical management of the aortoiliac occlusive disease. Patient selection for surgery should be based on an assessment of the patient's underlying conditions, functional limitations, and life expectancy. Particular attention should be given to those patients with the identified risk factors of cardiac, renal, or pulmonary disease. Almost half of the patients undergoing surgery for the aortoiliac occlusive disease have coronary artery disease [23]. Comorbidities such as cerebrovascular, hepatic, and hematologic, should also be evaluated [22].

Aortic or Bilateral Iliac Artery Occlusion

Aortoiliac Endarterectomy

Aortoiliac endarterectomy, the first arterial reconstruction performed in this region, was introduced by Wyllie in 1951 [1]. During the next decade, endarterectomy became the standard surgical treatment therapy for severe aortoiliac occlusive disease. The further introduction of prosthetic grafts led to the development of aortic bypass grafting techniques. The indisputable advantage of endarterectomy is the absence of a prosthetic graft, eliminating the risk of infectious complications associated with use of prosthetic grafts. Aortoiliac endarterectomy is technically more demanding than bypass surgery but can be an alternative for younger patients with longer life expectancy (Figure 9).

Figure 9. An aortoiliac endarterectomy.

Aortobifemoral Bypass

The “gold standard” of aortoiliac reconstructions is aortobifemoral bypass. The goal of this operation is the restoration of blood flow from the subrenal aorta to both common and deep femoral arteries.

Figure 10. Aortobifemoral bypass: an end-to-side anastomosis.

Figure 11. Aortobifemoral bypass: an end-to-end anastomosis.

The operation is performed under general anesthesia, mainly from the transperitoneal approach. For the purpose reverse, bifurcated prosthetic grafts are used. Dacron grafts are favored to the PTFE grafts. The proximal anastomosis is placed on the subrenal aorta, and the distal anastomoses are targeted at the femoral arteries. The proximal anastomosis is usually constructed in an “end-to-side” manner that enables restoration of the blood flow distally to the inferior mesenteric artery and also to the internal iliac arteries (Figure 10). The anastomosis is performed in an “end-to-end” manner in cases of concomitant aneurysmatic dilatation of the aorta (Figure 11). The disadvantage of the “end-to-end” anastomosis is the decrease of the blood flow to the inferior mesenteric and pelvic arteries that may lead to mesenteric or pelvic ischemia. The distal anastomoses are targeted to the common femoral artery. It is crucial to perform adjunctive profundoplasty to place the tip of the distal anastomosis at the deep femoral artery (Figure 12). This type of the distal anastomosis preserves the long term patency of bypasses, especially in the individuals with the occluded superficial femoral artery (SFA) [22].

The long term results of the aortobifemoral bypasses are excellent. The five-year patency is 85%-90% and the ten-year patency is 75-85% [22]. Perioperative mortality is low, about 1-2% [22].

Figure 12. Adjunctive profundoplasty.

Multilevel Occlusive Disease

In patients with synchronous aortoiliac occlusive and superficial femoral artery (SFA) disease, we prefer to perform the first step aortobifemoral bypass with adjunctive profundoplasty. Almost 80% of patients with multilevel occlusive disease manifest symptomatic improvement after aortobifemoral bypass grafting alone, and they do not require further revascularisation of SFA [24].

Retroperitoneal Approach

The retroperitoneal approach to the infrarenal aorta is a well-accepted alternative to the transperitoneal technique. This option may be advantageous in patients with a history of previous abdominal operations, or severe cardiopulmonary disease. The literature has not consistently supported reported benefits of reduced pulmonary morbidity and lower rates of postoperative bowel obstruction. The main disadvantage of the retroperitoneal approach

represents the difficulty in accessing the right renal and iliac arteries and the right groin, particularly in obese patients [25].

Unilateral iliac Artery Occlusion

Unilateral iliac artery occlusion can be treated endovascularly. When the lesion is classified as TASC C or D stage (Figure 13), surgery is the preferred option. Options of surgical therapy are:

1. Direct iliac endarterectomy
2. Iliofemoral bypass
3. Extra-anatomic cross over femorofemoral bypass.

Figure 13. Arteriography (angiography), aortoiliac occlusive disease. Multiple severe stenoses of iliac arteries. Occlusion of the left external iliac artery (marked by an arrow) and severe stenoses of the right common and external iliac artery.

1. The direct iliac endarterectomy can be considered in younger patients, similarly to aortoiliac endarterectomy. We can solve long occlusions of CIA and AIE. Direct iliac endarterectomy is performed from a retroperitoneal approach. Endarterectomy of the CIA is done from a longitudinal incision at the artery. Endarterectomy of the EIA can be done either from the groin by Volmar loop endarterectomy or from the longitudinal incision at the EIA. Vessels are sutured directly after the endarterectomy. Groin incisions are often necessary for both situations to fix the intimal flap at the CFA distally. The advantage of the procedure is the absence of any prosthetic material and reduced risk of infectious complications. After direct iliac endarterectomy, there is the remaining possibility to perform the aortobifemoral bypass. The disadvantages of the procedure are the facts that the operation is demanding from a technical point of view and necessity of the retroperitoneal approach. We chose this possibility in the case of the unilateral iliac lesion, which cannot be treated endovascularly, and the patients are fit for a retroperitoneal approach. This operation may be bringing therapy to the definitive aortobifemoral bypass.

2. The unilateral iliofemoral bypass is performed more rarely than the aortobifemoral bypass. Hence, it does not solve the apparent atherosclerotic stenosis at the aortic division and also has the disadvantages of using prosthetic material and demanding retroperitoneal approach. This procedure can resolve the situation when the direct iliac endarterectomy from the retroperitoneal incision is not technically feasible. This reconstruction is performed usually using dacron graft.
3. The femorofemoral cross over bypass is the most commonly used extra-anatomic bypass. The main advantage of the bypass is that it can be constructed from the inguinal incision. The reconstruction does not require a peritoneal or retroperitoneal incision and thus is less invasive. This bypass is an excellent solution for patients who are not fit for aortic surgery. The operation is started by inguinal incision at the site of the patent iliac and femoral artery. When the quality of the pulse is sufficient, we can perform contralateral inguinal incision and find the appropriate segment of the common femoral or the deep femoral artery with good outflow. The bypass is performed mainly with armored Dacron grafts and maybe in “U,” “inverted C” (Figure 14) or “S” configuration. We prefer the “S” configuration of bypasses when the anastomosis at the donor femoral artery is placed proximally to the distal anastomosis. In this situation the angle of the proximal anastomosis is more appropriate. The bypass may also be constructed with the great saphenous vein. We chose the great saphenous vein as the graft when there is a high risk of infection or when the inflow and outflow parameters for the reconstruction are not optimal (Figure 15). The venous cross over bypass is a better solution for patients with not optimal donor iliac artery and also with SFA occlusion at the donor or recipient site.

Figure 14. “Inverted C” configuration of a femorofemoral cross over bypass.

Figure 15. Arteriography (angiography): “U” configuration of a venous femorofemoral cross over bypass.

The perioperative mortality of femorofemoral cross over the bypass is dependent on patient selection but should be under 5% in elective operations. The primary and secondary patency of femorofemoral cross over bypass at five years is about 60% and 70%, respectively [22].

Complications after Aortoiliac Reconstructions

Early Complications

Morbidity after aortic surgery for the occlusive disease is reported at 17% to 32% [22]. Cardiac complications are the most common reason for mortality, followed by pulmonary complications [26]. Cardiac complications result from the hemodynamic stress associated with the operation and the obligatory fluid shifts in the early postoperative period. Myocardial infarction occurs up to 5%, and prevention is the use of the antiplatelet drug.

Pulmonary complications occur in elderly patients and those with chronic obstructive pulmonary disease, a history of smoking, or poor preoperative nutrition [27]. The incidence is up to 7%, and postoperative rehabilitation and exercises are essential in the prevention.

Renal failure can occur due to perioperative blood loss and hypotension after aortic de-clamping. This complication occurs in 1-8% and can lead to hemodialysis [22].

Bleeding is a severe complication after aortic surgery, occurs up to 2%, and can lead to hemorrhagic shock with fatal consequences when not treated [28]. The most dangerous is anastomotic bleeding that requires immediate surgery with additional hemostatic stitches at the anastomotic site. Aortic surgery can be associated with hypocoagulation status, especially when the heparin reversal is not complete. This situation can be treated conservatively with fresh frozen plasma. Bleeding, which continues after conservative treatment, requires surgery.

Acute limb ischemia occurs up to 3% after aortoiliac reconstructions and can be due to graft occlusion or distal embolization. The treatment is surgical thrombectomy of the graft.

Lesion of the ureter is another major complication after aortic surgery, which occurs only in 1% of cases and is caused by direct injury during the operation [22]. The treatment is the reconstruction of the ureter.

Left colon ischemia is another dangerous complication and can lead to left colon necrosis with fatal consequences. The incidence of complication is up to 2% [29]. It is crucial to preserve the patency of at least one or both the internal iliac arteries or inferior mesenteric artery.

Paraplegia after aortic surgery can occur in 0.25% of cases and is due to diminished blood flow in lumbar and internal iliac arteries during aortic clamping

Late Complications

Graft occlusion is the most common late complication. It can be seen in as many as 30% of patients after ten years [22]. Occlusion of the whole graft, in the case of the aortobifemoral bypass, is rare. Much more common is occlusion of only one limb. The reason is neointimal hyperplasia or the development of atherosclerosis at the distal anastomosis. The graft occlusion presents clinically as acute limb ischemia. The treatment is graft thrombectomy, and the stenosis of the distal anastomosis which usually requires an interposed graft at the next patent segment of the deep femoral artery.

Anastomotic false aneurysms are rare in the modern era compared with the early experience of aortic surgery, but they can be seen as a late complication in 1% to 5% of cases [30]. They appear secondary to a weakening in the suture line as a result of structural fatigue or fabric degeneration. However, they may be a first sign of the graft infection.

Graft infection is one of the most dangerous complications of aortic surgery and is associated with high morbidity and mortality. Incidence of graft infections is reported in up to 1.5% of cases [31]. The reasons for graft infections can be perioperative contamination of the graft with microbes. For example, perioperative contact with patient's skin can lead to graft infection. Gastrointestinal procedures concomitant to vascular surgery can also lead to perioperative contamination of the graft. Direct contact of the small intestine and the graft may lead to communication and graft-enteric fistula with the consequence of the graft infection. Also, repeated groin incisions may lead to graft infection. Graft infection leads to chronic sepsis, and the most dangerous complications are the graft-enteric fistula with severe bleeding into the gastrointestinal tract. The diagnosis is based on CT or PET-CT imaging. The graft infection is complicated to treat and is associated with mortality of up to 20% [31].

Only isolated groin infections can be treated with antibiotics, and vacuum-assisted closure device (VAC) Removal of the whole graft is often necessary. The continuity of the aortic flow and the blood supply to the lower limbs must be restored. The blood flow to the lower extremities can be ensured by an extra-anatomic axillobifemoral bypass or in situ bypasses with the graft constructed from the deep femoral vein. Another possibility of in situ reconstructions is to use human aortic allografts or xenografts, mainly bovine xenopericardial grafts. Intravenous antibiotic treatment is mandatory at least at six weeks. In the cases of graft-enteric fistula, the defect at the small intestine or duodenum must be sutured or resected [32].

ABDOMINAL AORTIC ANEURYSM: GENERAL CONSIDERATIONS

An enlargement of an artery to at least 1.5 times its standard diameter is defined as an aneurysm [33]. The expanding vessel elongates as well as dilates. A true aneurysm involves intima, media, and adventitia. A false aneurysm, also called pseudoaneurysm, is characterized by a disruption of the arterial wall, which does not include all layers of the wall, and a possible pulsatile hematoma not contained by the artery wall but by a fibrous capsule. A false aneurysm caused by infection is called a mycotic aneurysm. Aneurysm of the abdominal aorta (AAA) is dilatation of the abdominal aorta to over 3 cm in transverse diameter.

Epidemiology

Abdominal aortic aneurysms are found in 2% of the elderly male population. The incidence is higher of patients with coronary artery disease (5%). In the U.S., ruptured AAA is the 13th leading cause of death overall and the third leading cause of death in men's population older than 65 years [34]. As many as 50% of patients with femoral or popliteal aneurysms have aortic aneurysms. About 60% percent of patients with the AAA have an aneurysm in other localization, mainly iliac aneurysms, but also popliteal or thoracic. Ninety-

five percent of aneurysms of the abdominal aorta begins distally to the renal arteries. They are called infrarenal aneurysms of the abdominal aorta [33].

Etiology

Majority of AAAs are of atherosclerotic (degenerative) origin. The relationship of atherosclerosis to aneurysm creation is complicated, but both aneurysms and obliterative manifestations can be found in the same patient. Activation of metalloproteinases in the media can lead to proteolysis and degradation of the aortic wall [35].

Aneurysms of the abdominal aorta can also be of inflammatory origin and are associated with an inflammatory component, which often starts a fibrotic reaction around the aneurysm and can lead to ureteral obstruction as the process. The precise etiology of inflammatory aneurysms is not clear [36].

Infectious AAA may result from a primary infection of the aortic wall and also can be caused by blood-borne seeding of an infectious process. Infectious aortic aneurysms are caused mainly by the *Salmonella* species [33].

Also, injuries can lead to the formation of posttraumatic false aneurysms. A particular type of AAA are aneurysms caused by abnormalities of connective tissue as Marfan's syndrome and Ehlers-Danlos syndrome [33].

Risk Factors

Plenty of mechanisms have been proposed as the cause of abdominal aortic aneurysms. In terms of risk factors, cigarette smoking has a powerful influence on developing an aortic aneurysm, with an 8:1 preponderance of AAAs in smokers compared with nonsmokers. So-called "hard" risk factors for the development of AAAs are smoking, male gender, and hypertension [33]. Patients with AAA are elderly, and thus have more underlying diseases such as coronary artery disease, hypertension, and pulmonary disease.

Aneurysm Rupture Risk

Risk of rupture increases with the transverse diameter of AAA. Data derived from The United Kingdom Small Aneurysm Trial (UKSAT) have shown the most complex estimates of aneurysm rupture risk in patients randomized to nonoperative management. The UKSAT was the first randomized trial that compared early open repair with surveillance for AAAs. The study showed a low risk of rupture in aneurysms below 5cm in transverse diameter and relatively high risk of rupture in aneurysms in transverse diameter over 6.0cm (Table 1). The operative mortality of patients undergoing surgery was 5.8% in this trial [37]. The UKSAT, and also further studies showed that there is no benefit for surgery in asymptomatic aneurysms in diameter below 5.5 cm [37, 38]. This data led to current recommendations for surgical treatment in aneurysms over 5.5 cm in transverse diameter for men and over 5.0 cm in transverse diameter for women, or enlargement over 1.0 cm during one year [39].

Table 1. Range of rupture rates for a given diameter of AAA [33]

AAA diameter (cm)	Annual rupture risk (%)
3.0-3.9	0.3
4.0-4.9	0.5-1.5
5.0-5.9	1.0-11
6.0-6.9	11-22
over 7.0	over 30

ABDOMINAL AORTIC ANEURYSM: NON-RUPTURED

Clinical Presentation

The vast majority of non-ruptured AAA are asymptomatic. The finding of an AAA is during abdominal imaging for an unrelated condition. Sometimes patients may feel a pulsatile mass in the abdomen.

Symptomatic aneurysms are intact aneurysms which cause back pain due to pressure on nerves or erosion into vertebral bodies. The pain may irradiate to the abdomen, groin, or lower limbs. Severe pain in the absence of rupture may be present in cases of the rare inflammatory aneurysms that are surrounded by a perianeurysmal retroperitoneal inflammatory reaction. Eighty percent of aneurysms over 5 cm in transverse diameter are palpable as a pulsatile mass. AAA may present with peripheral microembolization to toes causing a “blue toe syndrome.”

Imaging Studies

Ultrasound is a first line method for initial confirmation of AAA and is also the least expensive. Repeated ultrasound examinations are cost-effective for observing small aneurysms.

Computed tomographic angiography is an essential imaging study for the diagnosis of AAA (Figure 16, 17). It provides a much more accurate measurement compared to ultrasound. CTA should be performed from the aortic root to iliac arteries because about 60% of AAAs have synchronous aneurysms, especially in the thoracic aorta or iliac arteries. CTA is crucial for the decision for the type of treatment and also for the follow-up. The disadvantage of CTA is the fact that CTA is more expensive than ultrasound and involves exposure to radiation and intravenous contrast material.

Magnetic Resonance Imaging (MRI) represents an alternative to CTA. The advantage is the absence of exposure to ionizing radiation. The disadvantages of MRI are high cost and limited availability. MRI is a perfect solution for patients with a heavy allergy to iodine.

Indications for operation [39]:

1. Asymptomatic AAA is indicated to surgery
 - a) When an expansion of asymptomatic AAA is more than 1 cm in 12 months is present.
 - b) When the diameter of asymptomatic AAA is more than 5.5 cm in men

c) When the diameter of asymptomatic AAA is more than 5.0 cm in women

2. Symptomatic AAA

Symptomatic AAA of any diameter without proven rupture should be operated on within 48 hours.

3. Ruptured AAA

Ruptured AAA of any diameter should be operated on immediately.

Figure 16. CTA, aneurysm of the abdominal aorta in a transverse scan.

Figure 17. CTA, 3-dimensional reconstruction of aneurysm of the abdominal aorta.

Preoperative Management

Elective open repair is associated with high mortality rate of up to 5% [7]. Thus, patients for elective repair should be carefully prepared. Evaluation of cardiac, pulmonary, renal, and

metabolic status should be performed. Hypertension and metabolic diseases should be compensated for. In patients with AAA and concomitant stenosis of the internal carotid artery (ICA) of over 70%, a carotid endarterectomy of ICA before aneurysm repair should be performed. Older patients not fit for open surgery should be considered for endovascular treatment [39].

Operation

Operation because of AAA is performed under general anesthesia and starts with laparotomy. The use of cell-savers is recommended, then this device may decrease the postoperative mortality and also the rate of complications, especially in patients with ruptured AAA [39]. After mobilization of the duodenum, we reach the aortic neck. Then we prepare both iliac arteries. When iliac arteries are not dilatated over 2.5 cm in transverse diameter, it is not necessary to replace the iliac artery. After administration of heparin, we can clamp aorta subrenally and common iliac arteries below the aneurysm. After the opening of the aneurysmatic sac, lumbar arteries must be sutured to stop the backflow bleeding. Afterward, we can reconstruct the aorta with a tube Dacron graft from the subrenal part to the aortic division (Figure 18, 20).

When also iliac arteries are dilatated over 2.5cm, an aortobiiliacal reconstruction with a bifurcated (reverse Y-shaped) Dacron graft should be performed (Figure 19, 21). The distal anastomoses are placed at the division of the common iliac artery. When the aneurysmatic dilatation proceeds at the internal iliac arteries, they must also be ligated. It is crucial to preserve the patency of at least one or both internal iliac arteries or inferior mesenteric artery, otherwise left colon ischemia may occur.

Figure 18. Surgical repair of AAA with a tube graft.

In cases of the short subrenal neck, we must place an aortic clamp above one or above both renal arteries to safely construct proximal anastomosis. In the case of suprarenal clamping, the proximal anastomosis and restoration of the blood flow to renal arteries should be completed within 30 minutes. Afterward, we cover the graft with aneurysmatic tissue to

avoid the direct contact between the graft and small bowel to prevent secondary graft-enteric fistula.

Figure 19. Surgical repair of AAA with a bifurcated graft.

Figure 20. Operation: surgical repair of AAA, using a tube Dacron graft.

Figure 21. Operation: surgical repair of AAA, using a bifurcated Dacron graft.

Complications

Mortality and Early Complications

Historically, open surgical repair of AAA was associated with one of the highest mortality rates among all elective surgical operations; mortality rates were reported up to 7.5% in the 1990's [42]. However, with improving anesthesiologic methods and surgical technique mortality rates after elective open surgical repair have decreased and now range from 3.0% -5.0 % [33].

Early, and late complications after open surgical repair of AAA are very similar to early complications after aortic reconstructions due to aortoiliac occlusive disease. Postoperative severe complications occur by up to 28% [43].

Cardiac, pulmonary, and renal complications are the most common complications after open surgical repair of AAA. They are associated with prolonged anesthesia, aortic clamping, blood loss, and hypotension after aortic de-clamping.

Bleeding after open surgical repair of AAA occurs in up to 1.2% of cases [43] and can be from anastomoses, lumbal, iliac arteries or veins or retroperitoneal tissue. The bleeding is often massive and requires a prompt surgical revision. All anastomoses and the retroperitoneal surface should be checked before closing the retroperitoneum and abdomen. Heparin reversal is also essential in the prevention of the postoperative bleeding.

Ischemia of the left colon is also severe. The incidence is up to 6% and occurs especially when also the internal iliac arteries are involved in the aneurysmatic process. It is crucial to ensure the blood supply to at least one internal iliac artery or to perform reinsertion of the inferior mesenteric artery (IMA) to the graft during reconstruction. Otherwise, we risk fatal necrosis of the left colon [43].

Acute limb ischemia, lesion of ureter, and paraplegia may also occur after open surgery of AAA similarly as after aortoiliac reconstructions due to aortoiliac atherosclerosis [43].

Late Complications

The graft occlusion is not so typical after the open surgical repair of AAA as in arterial reconstructions due to aortoiliac atherosclerosis. The main reason is that the patients with AAA have mainly good out-flow compared to the patients with occlusive aortic disease.

Severe complications are graft infections that occur in up to 1.5% of cases [32]. The graft infection is mainly due to the secondary graft-enteric fistula, when there was a contact between the small intestine and the prosthetic graft left during the primary operation. The connection between the small intestine and the graft leads to the graft-enteric erosion and graft-enteric fistula with prosthetic graft infection afterward. The graft infection is a life-threatening condition, as it can lead to severe bleeding from anastomosis. It often requires the entire graft removal and in situ reconstructions mainly with deep femoral veins or the extra-anatomic bypass. The mortality of graft infections is high, reported up to 20% [43].

Isolated Iliac Artery Aneurysms

Iliac artery aneurysms generally occur in conjunction with AAA in about 40-50% of cases. Isolated iliac aneurysms are unusual. The physical examination can suggest the

diagnosis of large (>4cm) iliac artery aneurysms. Most symptomatic iliac aneurysms can be palpated as pulsatile masses on abdominal or rectal assessment. Iliac aneurysms are usually found incidentally on ultrasound or CT. Isolated aneurysm of the common iliac artery is indicated for a repair when the transverse diameter is more than 3.5cm [33]. The main risk of this aneurysm is, similarly to AAA, a rupture with massive bleeding and the mortality up to 40 % [33].

An isolated iliac aneurysm can be treated with a tubular Dacron graft, mainly from the retroperitoneal approach. More common is aneurysm of iliac artery associated with dilatation of the abdominal aorta or the aneurysm of the abdominal aorta and in such situations, reconstruction with a bifurcated Dacron graft is necessary[40]. When the aneurysm is anatomically convenient, endovascular treatment can also be considered.

ABDOMINAL AORTIC ANEURYSM: RUPTURED

Epidemiology

Mortality of ruptured AAA is high, up to 75%. Approximately one-half of patients with a rupture of AAA do not survive transport to the hospital, and only one half of those who survived transport will survive the perioperative period [40].

Clinical Presentation

Patients that present with sudden, severe abdominal pain that usually irradiates into the back and occasionally into the inguinal region. Shock can be profound, manifested by peripheral vasoconstriction, hypotension, and anuria. Unfortunately, the classic triad of pain, a pulsatile abdominal mass, and hypotension are not always present. Rupture is a first presentation of AAA in about 80% of cases. A rare form of rupture is perforation of AAA into the vena cava inferior, causing sudden onset of heart failure [33].

Imaging Studies

A first line imaging study for confirmation of a ruptured AAA is ultrasound. Finding of aneurysmatic dilatation and perianeurysmatic hematoma is typical for the rupture. In hemodynamically stable patients, we can consider CTA for better evaluations of relationship to renal arteries or the diameter of iliac arteries (Figure 22). However, hemodynamically unstable patients can further CTA lead to a fatal delay, so in such an unstable patient, we indicate an urgent operation based only on ultrasound examination.

Figure 22. CTA of a ruptured AAA, hematoma in retroperitoneum is marked by an arrow.

Preoperative Management

Thus, the crucial fact in preoperative management in patients with a ruptured AAA is to avoid any delay. Patient with a ruptured AAA should undergo surgery as soon as possible. That is why we prefer to operate on patients with a ruptured AAA based only on ultrasound because the CTA may represent further delay. A delay of 1 minute represents an approximately 1% increase in mortality. It is very important not to raise the systolic blood pressure over 100 mm Hg since this may increase bleeding. Aggressive volume resuscitation in preoperative management of ruptured AAAs before proximal aortic control leads to increased postoperative mortality [41]. Recommended is hypotensive volume resuscitation with keeping blood pressure at about 80-90 mm Hg [39].

Operation

The operation for a ruptured AAA is similar to the elective cases. Cell savers are mandatory [39]. Proximal aortic clamping should be performed as soon as possible. In cases when we cannot obtain proximal aortic control subrenally, there is a possibility of supraceliac aortic clamping beneath the diaphragm. The supraceliac clamping can stop bleeding, but it should be as brief as possible, then this may lead to visceral ischemia. Systemic heparinization is generally avoided during repair of ruptured AAA, although heparinized saline solutions can be administered directly into the common iliac arteries to reduce distal thrombosis [40]. The reconstruction may be performed with a tube Dacron graft when iliac arteries are not involved (Figure 18). In the case when iliac arteries are dilated over 2.5cm, reconstruction with a bifurcated Dacron graft should be done (Figure 19).

Mortality and Complications

Despite advances in anesthesiology, critical care, and surgical techniques, the mortality of ruptured AAA still remains at approximately 50%. Usage of cell savers and the concentration

of operations to the high volume centers are factors that may improve post operational outcomes [39, 40].

Hypotension and extensive blood loss during rupture of AAA can lead to cardiac complications. Myocardial infarction, arrhythmias, congestive heart failure, and cardiac arrest are life-threatening situations that can increase the mortality after aortic rupture. Preexisting coronary artery disease can increase the risk of cardiac complications [40].

Acute respiratory distress syndrome (ARDS) develops in up to 47% of cases. Preexisting chronic obstructive pulmonary disease is a risk factor for ARDS. ARDS is associated with a mortality rate of up to 64% [44].

Rupture of AAA can lead to renal dysfunction, and renal failure, and approximately 10-40% of patients require dialysis (11%-40%). Renal dysfunction is increased in those with suprarenal cross-clamping, longer duration of aortic cross-clamping, preexisting renal insufficiency, shock, and increased age [40]. Liver failure can also occur in the postoperative course. Multiorgan failure (MOF) may occur up to 35% with very high mortality. The incidence of death in patients with postoperative MOF is reported to range from 64% to 93% [40].

One of the most severe complications is postoperative bleeding. It may be due to prolonged hypothermia and coagulopathy after blood loss associated with rupture. The incidence of postoperative bleeding after the open surgical repair of ruptured AAA is up to 14%. Quick operation, correction of hypothermia, supplementation of blood loss, coagulation factors, and correction of acidity as soon as possible is the primary prevention of postoperative coagulopathy. Usage of heparin during operations because of ruptured AAA should be avoided. Spinal cord and left colon ischemia can also occur. The incidences are higher compared with the elective open surgical repair due to hypotension and blood loss associated with the aortic rupture.

The rate of the highest grade colonic ischemia is 10% and is associated with a mortality rate of 50% [45]. The overall risk of spinal cord ischemic complications is reported to be 2.3% [45].

Abdominal compartment syndrome can also occur after the open surgical repair of ruptured AAA. The incidence is up to 10% [40] and is associated with retroperitoneal hematoma and edema. In the case of abdominal compartment syndrome, delayed abdominal closure should be planned [40].

ABDOMINAL AORTIC ANEURYSM: ENDOVASCULAR THERAPY

General Considerations

Endovascular aneurysm repair (EVAR) means that the stent graft is inserted into an aneurysm and is sealed above and below the aneurysm, in so-called sealing zones. Juan Parodi, in 1991, was the first who used stentgraft for the treatment of an aortic aneurysm [46]. From there the field of vascular surgery has been changed and the era of endovascular aneurysm repair (EVAR) was born. Today in the U.S, about 60% of all elective cases of aneurysm of abdominal aorta are treated by EVAR.

Endovascular repair requires that the aorta proximal to the aneurysm have a cylindrical configuration for at least 1.5 cm to allow adequate sealing of stentgraft and iliac arteries that are of sufficient size and limited tortuosity so that the device can be introduced from the femoral arteries (Figure 23). Only 40-60% of aneurysms are anatomically suitable for endovascular treatment. The assessment of anatomical suitability of an AAA is based on CTA.

Figure 23. A stent graft in AAA.

Endoleak

The essential intermediate or long-term adverse outcome is persistent perfusion of the aneurysm (endoleak). These are divided into five types of denoting clinical importance.

A type I endoleak means ineffective proximal or distal sealing. Endoleak I is the most serious since it can lead to aneurysmatic sac enlargement and sac rupture even with an implanted stentgraft. Type I endoleak can be divided into two subtypes. Type IA endoleak means the leak through the proximal sealing zone, and type IB endoleak is the leak through the distal (iliac) sealing zone.

A type II endoleak means that the aneurysm is filled by backflow from patent lumbar arteries or the inferior mesenteric artery. Because of backflow, they have relatively low pressures and do not lead to aneurysm enlargement.

Leaking through the components of the stentgraft is a type III endoleak. This can lead to expansion of the aneurysm and requires urgent repair, similar to endoleak type I.

Type IV is caused by graft fabric porosity, which may result in a generalized mild blush of contrast medium within the aneurysm sac. This type of endoleak occurs less frequently with current-generation stent grafts and is observed within 30 days of graft implantation.

Type V endoleak, (endotension) is defined as elevated sac aneurysm pressure without a visible endoleak. It is believed that the etiology is an undetected endoleak or transmission of systemic pressure through the thrombus.

Complications of EVAR

One of the most severe complications is the migration of the graft, with the incidence up to 8.4%, and that refers to the caudal movement of the stent graft, which may lead to loss of proximal fixation and result in type IA endoleak with further growth of the aneurysm and increased risk of rupture. It requires the proximal stent graft extension or surgical explantation of the graft.

Occlusion of the stent graft limb occurs after 3% to 7% of EVAR procedures over a nine-month to the four year period [46]. It is more frequent in patients with the aortoiliac occlusive disease and stenotic or tortuous iliac arteries. This type of complication can be treated endovascularly or surgically by performing a femorofemoral cross over bypass.

Neck dilatation, the juxtarenal part of the aorta dilates not as common as the infrarenal aorta, but can also dilate following EVAR, that results in migration and type I endoleak and risk of rupture [46]. Neck dilatation is treated similarly as the graft migration with the proximal extension or with the open surgical graft explantation.

Pelvic ischemia can manifest as buttock claudication, buttock necrosis, spinal cord ischemia, left colon, and erectile dysfunction. It occurs as a consequence of occlusion of one or both internal iliac arteries in the presence of an aneurysm of the common or internal iliac artery [46].

Occlusion of the renal artery occurs either from inadvertent stent graft coverage of the renal artery or from its embolization. Stent graft coverage most commonly occurs periprocedurally. Occlusion of both renal arteries may lead to renal failure with hemodialysis. The treatment can be endovascular or renal stenting to preserve renal artery flow. If this is not possible, open hepatorenal bypass should be performed [46].

Infection of the stent-graft is rare, with a small incidence of 0.2% to 0.7%. Treatment can be conservative, or when the conservative treatment is not successful, sepsis can lead to the necessity of graft removal [46].

Results

Four randomized trials were performed to compare open surgery with EVAR for treatment of AAA: the EVAR I (Endovascular aneurysm repair) trial, DREAM (Dutch Randomized Endovascular Aneurysm Management) trial, OVER (Open Versus Endovascular Repair) trial, and French ACE (Anevrisme de l'aorte abdominale, Chirurgie versus Endoprothese) trial [39]. The results of those randomized trial were similar. EVAR was associated with a lower 30 day postoperative mortality (0.5-1.7%) compared with the mortality of open surgical repair (1.3-4.7%) in all four of those trials. The early survival benefit was lost after three years in all the studies. The latest outcomes of the EVAR I study showed significantly higher mortality in the EVAR group after eight years, mainly associated with the aneurysm sac rupture [8]. The EVAR, DREAM, and the ACE trial showed significantly higher re-intervention rate in the EVAR group [39].

Thus, EVAR should be considered in all patients. It is reasonable to suggest an open surgery first strategy in younger, fit patients with a life expectancy over ten years [39].

SPLANCHNIC ARTERIES

Splanchnic arteries represent the celiac axis (CA), superior mesenteric artery (SMA), inferior mesenteric artery, and renal arteries (RA).

The celiac axis divides shortly after its origin into the three main arteries: the common hepatic artery, splenic artery, and left gastric artery. The celiac axis ensures blood supply to the organs of the upper abdomen such as the liver, stomach, duodenum, spleen, and pancreas.

The superior mesenteric artery is a crucial vessel for blood supply to abdominal organs like the small intestine, right, and transverse colon. The pancreaticoduodenal arteries represent collateral between the CA and SMA.

The inferior mesenteric artery supplies the left colic flexure, left colon, and rectum with blood — Arcus Rioli represents collaterals between the SMA and IMA (Figure 24). In case of the patent the superior mesenteric artery and internal iliac arteries, the IMA may be ligated.

The renal arteries ensure the blood supply to both kidneys.

Figure 24. Splanchnic blood supply.

Occlusion of Splanchnic Arteries

Acute Mesenteric Ischemia

Sudden occlusion of the SMA presents as acute mesenteric ischemia. The main reason for acute occlusion is atrial fibrillation in 50%, thrombosis the atherosclerotic plaques in about 30% of cases, and the rest can be caused by functional spasms or aortic dissection type Stanford B [47]. Acute occlusion of the other splanchnic arteries is rarely noted.

Acute mesenteric ischemia is a highly morbid disorder. Patients present classically with excruciating diffuse abdominal pain, out of proportion to physical finding. Acute mesenteric

ischemia leads to bowel paralysis, and later to ischemia of the bowel that proceeds to the bowel necrosis with bowel perforation and peritonitis. The diagnosis can be difficult and is based on ultrasound or CTA. Also, arteriography can confirm the diagnosis of acute occlusion of the SMA.

Treatment

When the reason for acute mesenteric occlusion is embolism, an embolectomy of the SMA is the treatment option. When the embolectomy is performed within 6 hours, intestinal ischemia is reversible and intestinal resection is not necessary. When the embolectomy of the SMA is done 4-6 hours after the acute occlusion, then the bowel ischemia is mostly irreversible, and the gut resection is not necessary. After the embolectomy, the second look laparotomy should be performed within 48 hours to evaluate the vitality of the intestine. If inevitable, the bowel resection can be done during the second look operation. Thrombosis of the SMA cannot be treated by simple embolectomy. Thrombosis of the superior mesenteric artery at atherosclerotic plaques may be rarely revascularized, and a massive bowel resection is necessary in the majority of cases. In the rare case when the small intestine is still vital, a bypass can be considered. The bypass can be antegrade from the suprarenal aorta to the SMA beneath the occlusion. Alternatively, the other possibility is a retrograde bypass, mainly from the right common iliac artery to the SMA. In cases when the bowel resection might follow bypass surgery, we prefer a venous bypass with the graft from the great saphenous vein, hence the consecutive bowel resection might be a risk factor for the infection of the prosthetic graft.

The mortality rate of acute mesenteric ischemia remains high. Patients who require massive bowel resection survive rarely or, if they survive, can develop the incapacitating short-gut syndrome [48].

Chronic Mesenteric Ischemia

Atherosclerosis is the cause of obstructive lesions in the visceral arteries in the vast majority of cases. Vasculitis (e.g., lupus erythematosus, Takayasu disease) is much less frequent [49]. The superior mesenteric artery is crucial for the blood supply to abdominal organs. Chronic stenosis or occlusion of the SMA can lead to chronic mesenteric syndrome. Stenosis or occlusions of the celiac axis can be asymptomatic.

The disease clinically presents with pain, which characteristically appears 15-30 minutes after the beginning of a meal and lasts for an hour or longer. Pain is occasionally so severe and prolonged that opiates are required for relief. The pain leads to the fear of eating, and weight loss is characteristic for the diagnosis. The disease is sometimes called abdominal angina.

The diagnosis is based on CTA or arteriography. Arteriography in the anteroposterior and especially the lateral projections demonstrate both the arterial lesion and the patterns of collateral blood flow (Figure 25). CTA or MRA can also confirm the diagnosis. Many gastrointestinal diseases can have similar symptoms as chronic pancreatitis or chronic gastritis, so before setting of the diagnosis of chronic mesenteric ischemia other conditions with the same clinical presentation should be excluded.

Figure 25. Arteriography (angiography): stenosis of the celiac axis (lateral projection).

Treatment

Treatment options are targeted to the SMA as the main splanchnic artery. The attempts of revascularization of the CA should be considered only after revascularization of the SMA.

Percutaneous transluminal angioplasty and stenting of the SMA or the CA have gained acceptance as the first line of therapy for mesenteric ischemia.

Surgical revascularization of the superior mesenteric and coeliac axis is performed when interventional treatment is not possible or was completed and failed. Either endarterectomy or bypass surgery can be done to obtain surgical revascularization of the SMA. Endarterectomy is reserved for short stenoses or occlusions in the origin of the SMA. When more extended occlusions are present, bypass surgery is indicated. The bypass can be antegrade, targeted from the suprarenal aorta retropancreatically at the celiac axis (Figure 26) or the SMA. The other possibility is a retrograde bypass from the distal aorta or the common iliac artery at the SMA below the occlusion (Figure 27). The antegrade bypass has better inflow from the suprarenal aorta but is more technically demanding. Suprarenal origin grafts are not ideal for patients with compromised pulmonary or cardiac functions or those with extensive atherosclerosis or calcification of the supraceliac aorta. The retrograde bypass has worse inflow from the common iliac artery or the distal aorta but is technically easier to perform and is better for higher risk patients. The long term results are similar, so both techniques are possible [50].

The surgery of the CA should be performed only in patients with the patent SMA and persistent mesenteric symptoms. Firstly, an attempt for interventional treatment should be performed. When this is not possible, open surgery should be considered. Revascularization of the CA can be done by transaortic endarterectomy and antegrade or retrograde bypass. When the concomitant SMA atherosclerosis is present, the bypass can be targeted at both arteries, the SMA and CA. The operation should be avoided in patients with acute vasculitis as the underlying cause of mesenteric ischemia, high-dose steroids, and immunosuppressive agents are indicated instead [49].

Figure 26. An antegrade aortoceliac bypass.

Figure 27. A retrograde aorto-superior mesenteric artery bypass.

Renovascular Disorders

Atherosclerosis characteristically produces stenosis at the orifice of the main renal artery. The lesion usually consists of aortic atheroma. Renal artery stenosis is more common in males over age 45 and is bilateral in about 95% of cases. Fibromuscular dysplasia usually involves the middle and distal thirds of the main renal artery and may extend into the distal thirds of the main renal artery and may extend into the branches [47]. Fibromuscular dysplasia is typical for fertile women.

Clinical Findings

Most patients are clinically asymptomatic, but irritability and emotional depression are seen in a few. Persistent elevation of the diastolic pressure is often the only abnormal physical finding. Renal atherosclerosis can lead to declining renal function and chronic renal failure. Noninvasive or minimally invasive imaging of the renal arteries is justified when the patient has a precipitous drop in blood pressure or decreased renal function with an ACE inhibitor. Renal arteriography is the most accepted method for delineating the obstructive lesion [51].

Treatment

Patients with renovascular hypertension require aggressive medical treatment and management of modifiable risk factors. Percutaneous transluminal angioplasty and stenting of renal arteries is the preferred procedure for most patients. In the very young, surgery is still the primary mode of treatment due to concern regarding the long-term durability of angioplasty and stenting. Surgery is indicated in patients with renovascular hypertension, which is refractory to medical or endovascular treatment or as an attempt for salvage of renal functions. Surgical repair also is required for failed angioplasty and stenting. Surgery represents either transaortic endarterectomy of the origin of the renal artery or bypass surgery (aorto-renal bypass) [47].

Splanchnic Artery Aneurysms

Aneurysms of splanchnic arteries are a rare condition, but they require clinical attention because of their lethal nature. The incidence of splanchnic arteries aneurysm in the general adult population is estimated to range from 0.1% to 2% [53].

Splenic Artery Aneurysms

Splenic artery aneurysms are the most common, and they account for more than 60% of splanchnic artery aneurysms. Women are affected four times more than men. The diagnosis is based mainly on CTA (Figure 28). Aneurysms of splenic artery manifest with rupture, which leads to massive intraperitoneal bleeding with sudden hemorrhagic shock. Bleeding from a ruptured aneurysm of the splenic artery can be fatal. Rupture during pregnancy tends to occur in the third trimester and is associated with a 75% maternal death rate and 90% fetal death rate [52].

The diagnosis is based on CTA or ultrasound examination. Intervention is indicated for patients with aneurysms more than 2 cm in transverse diameter or for patients with symptomatic aneurysms. Endovascular repair with covered stent grafts is ideal with the use of microcatheters. Laparoscopic ligation of the artery is also feasible. When endovascular treatment is not possible, surgical resection of aneurysm and replacement with a venous or prosthetic graft is the treatment of choice [52].

Figure 28. CT angiography of aneurysm of the splenic artery.

Aneurysms of Other Splanchnic Arteries

Hepatic artery aneurysms account for 20% of splanchnic artery aneurysms. There is a 2:1 male-to-female ratio.

Aneurysms of superior mesenteric artery account for 5% of all splanchnic artery aneurysms. Indication for the treatment is a size of more than 2 cm in transverse diameter. Operative therapy for mycotic superior mesenteric artery aneurysms includes ligation if there are adequate collaterals or replacement with a segment of the autogenous vessel.

Renal Artery Aneurysms

This uncommon aneurysm occurs in less than 0.1% of the population and is often associated with hypertension.

Aneurysms of splanchnic arteries and aneurysms of renal arteries are generally indicated for the treatment when they are above 2cm in transverse diameter or when they are symptomatic. The main complication of them is fatal bleeding. Diagnosis is based mainly on CTA. Treatment method of choice is an endovascular intervention. When endovascular treatment is not possible, open surgical treatment is necessary.

Chapter 288

CAROTID AND VERTEBRAL ARTERIES

Vladimir Katuch*, MD, PhD

Department of Neurosurgery, Medical Faculty of Safarik University
and University Hospital, Košice, Slovakia

ABSTRACT

Stroke is the second most frequent reason for death in the world and the most frequent reason for disability of the older population in developed countries. There are more than 150,000 new strokes in the UK each year [1, 2]. Of these, one in eight is fatal within 30 days, while one in four is fatal within a year [2]. Approximately 15% of ischaemic strokes are preceded by a transient ischaemic attack (TIA). Thromboembolism from an ipsilateral carotid artery stenosis is responsible for about 20% of all strokes [3, 4]. Two landmark randomised trials: the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST), demonstrated the benefit of performing carotid endarterectomy in symptomatic patients [5, 6].

Keywords: carotid artery surgery, carotid occlusive disease, carotid endarterectomy, surgical treatment, postoperative complication

INTRODUCTION

Stroke is the second largest cause of death in the world, causing 6,700,000 deaths each year, [1, 2] and is the fourth most significant cause of death in the UK [1-3]. There are more than 150,000 new strokes in the UK each year. Of these, one in eight is fatal within 30 days, while one in four is fatal within a year [2]. Approximately 15% of ischaemic strokes are preceded by a transient ischaemic attack (TIA). With the aging of the general population and the availability of noninvasive imaging studies, carotid artery stenosis is a disease commonly

* Corresponding Author's Email: vladimir.katuch@upjs.sk.

seen in general medical practice. Thromboembolism from an ipsilateral carotid artery stenosis is responsible for about 20% of all strokes [3, 4].

Treatment alternatives are primarily between medical management, carotid endarterectomy, and endovascular techniques as combined angioplasty and stenting. Carotid endarterectomy (CEA) is the “gold standard” for treatment of patients with symptomatic severe or moderate stenosis since the results of the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery.

Trial (ECST) was published nearly two decades ago [5, 6]. Perioperative stroke, defined as any stroke that occurs within 30 days after carotid endarterectomy, remains a known complication of carotid endarterectomy in patients with symptomatic and asymptomatic carotid stenosis. Numerous clinical trials have established rates of perioperative stroke, showing a range of 3.5%–5.5% for symptomatic patients [7, 8] and 1.4%–2.5% for asymptomatic patients [9–11]. Based on these findings, international guidelines increasingly recommend that carotid endarterectomy be performed within two weeks of an ischaemic cerebrovascular event (TIA or minor stroke) in symptomatic patients with ipsilateral high- (70–99%) or moderate-degree (50–69%) carotid artery stenoses [11–15].

PATHOPHYSIOLOGY OF CAROTID ARTERY STENOSIS

Atherosclerotic plaques begin to form in the carotid artery at 20 years of age. In the extracranial circulation, plaques typically start on the back wall of the common carotid artery (CCA). As they enlarge, they encroach on the lumen of the internal carotid artery (ICA). The risk of stroke correlates with the degree of stenosis and with certain types of plaque morphology and is also increased in hypercoagulable states and with increased blood viscosity. Vulnerable plaques are atherosclerotic plaques likely to cause thrombotic complications or those that tend to progress rapidly (Figure 1). Criteria for vulnerable plaques include intimal thickening, plaque fissure, lipid/necrotic core with thin fibrous cap, calcification, thrombus, intraplaque hemorrhage, and outward remodeling. Some of these features can be identified with high-resolution MRI [16–18].

The human body has adequate innate protection against stroke and brain injury from vascular ischemia. The circle of Willis ensures that there is significant collateral circulation, which protects the brain from infarction due to proximal vessel occlusion. With more distal blockage, however, infarction is the rule rather than the exception. The size of infarction depends directly on the availability and size of pial–pial collaterals. Collateral flow is essential, as many patients with symptomatic stroke have evidence of previous infarction that remained small and asymptomatic due to the presence of collateral flow. The ischemic injury occurs under many different circumstances, most commonly thromboembolism or atherosclerotic disease. There are many other causes, including trauma, vascular inflammatory diseases, hemorrhage, hypercoagulable states, and venous thrombosis [16–19].

In contrast to other tissues, the brain is subject to several properties, such as its strict reliance on glucose and oxygen as an energy substrate, autoregulation of blood flow, and presence of the blood-brain barrier, that makes ischemia a very complex and multifactorial process [18–20].

Figure 1. Vulnerable carotid plaque after endarterectomy, ulceration in the plaque is marked by an arrow.

The terms stroke and cerebrovascular accidents are generally synonymous; they entail an acute neurologic deficit of a vascular etiology caused by ischemia or hemorrhage. The brain meets its metabolic demands solely by utilizing glucose and oxygen. These must be continuously delivered as the brain has virtually no energy reserve. Ischemia occurs when the delivery of either glucose or oxygen fails to meet the metabolic demand of the tissue. Hypoxia refers to decreases in the partial pressure of oxygen, whereas anoxia suggests the complete absence of oxygen in blood flow delivered to the tissue. Cerebral infarction occurs after the death of neuronal or glial cells in the affected region [21, 22].

Ischemia can be classified as either complete or incomplete, and global or focal. Global ischemia, such as that caused by cardiac arrest, affects blood flow to all areas of the brain similarly. There is little opportunity for collateral supply and regional variations in susceptibility to ischemia cause variability in the volume of infarction. The duration of global ischemia that is compatible with life is generally quite brief, and the deficits sustained during anoxic brain injury after cardiac arrest are often severe [23-25].

Focal ischemia is most often thromboembolic but also results from subarachnoid hemorrhage, intracerebral hemorrhage, and trauma. In general, focal ischemia produces less severe and more focal deficits than global ischemia. The volume of the infarct is defined not only by the vulnerability of specific populations of cells but also the variability and competence of collateral blood flow to the affected area (Figure 2) [16-19].

Figure 2. CT: ischemic brain lesion, 2.0 x 2.8 cm in diameter.

Collateral Circulation for ICA Stenosis/Occlusion

The effects of ICA stenosis/occlusion may be improved by collateral blood flow. Potential alternate routes for blood to reach brain tissue include [16]:

- 1) Flow through the circle of Willis
 - a) From contralateral ICA through the anterior communicating artery
 - b) From forwarding flowthrough the ipsilateral posterior communicating artery
- 2) Retrograde flow through ophthalmic artery parasitizing blood from both external carotid arteries (ECA) via:
 - a) facial artery – angular artery – dorsal nasal artery – and medial palpebral artery
 - b) maxillary artery
 - c) transverse facial artery – lateral palpebral artery
 - d) superficial temporal artery – supraorbital artery
- 3) proximal maxillary artery – anterior tympanic artery – a caroticotympanic branch of ICA
- 4) cortical-cortical anastomoses
- 5) dural – leptomeningeal anastomoses

Collateral Circulation for Vertebrobasilar Stenosis/Occlusion

Available collaterals depend on the site of occlusion. In basilar artery occlusion, collateral flow is via posterior communicating arteries or anastomoses between the superior cerebellar artery and the posterior inferior cerebellar artery. In proximal vertebral artery occlusion, the collateral flow is via a) ECA – occipital artery – muscular branches of the vertebral artery, or b) Thyrocervical trunk – ascending cervical artery – direct connection or spinal radicular arteries – vertebral artery, or c) contralateral vertebral artery and ascending cervical artery via spinal radicular branches and anterior spinal artery [16].

Stroke in Young Adults

Only 3% of ischemic strokes occur in patients under 40 years of age. Over 10% of ischemic strokes occur in patients under 55 years [16, 26]. Incidence is 10 per 100,000 persons age 35-44 years, and 73 per 100,000 persons for age under 55 years. In etiology, trauma is the most common cause of strokes (22%) in patients under 45 years [27]. Most of the rest are covered by the small number of etiologies listed below [16, 26-28]:

- 1) Atherosclerosis: 20%, but less common than in the older population
- 2) Embolism with recognized source: 20%
 - a) Cardiac origin is the most common
 - b) Fat embolism syndrome
 - c) Paradoxical embolism
 - d) Amniotic fluid embolism

- 3) Vasculopathy: 10%
 - a) Inflammatory – Takayasu’s, infective like tuberculosis or syphilis, or ophthalmic zoster, amphetamine abuse, mucormycosis or associated with systematic disease
 - b) Non-inflammatory – fibromuscular dysplasia, carotid or vertebral artery dissections, moyamoya disease, homocystinuria
- 4) Coagulopathy: 10%
- 5) Peripartum 5%
- 6) Miscellaneous cases: 35%
 - a) Uncertain etiology
 - b) Oral contraceptives
 - c) Venous thrombosis
 - d) Migraine
 - e) Cocaine abuse

SYMPTOMS OF ATHEROSCLEROTIC CAROTID ARTERY STENOSIS

Carotid artery lesions are considered symptomatic if there are one or more lateralizing ischemic episodes appropriate to the distribution of the lesion. A lesion is considered to be asymptomatic if the patient only has non-specific visual complaints, dizziness, or syncope not associated with TIA or stroke. The majority (80%) of atherothrombotic strokes occur without warning symptoms. Asymptomatic carotid stenosis is usually discovered as a carotid bruit. Accuracy of a bruit in predicting ICA is 50-83% and sensitivity is as low as 24% [29, 30]. The symptomatic carotid disease may present as a TIA reversible ischaemic neurologic deficit (RIND) or stroke with any of the following findings:

- 1) Retinal insufficiency or infarction (central retinal artery is a branch of the ophthalmic artery)

Ipsilateral Monocular Blindness

- a) Maybe temporary: amaurosis fugax, also known as transient monocular blindness, four types:

Type I – embolic, described “like a black curtain coming down” in one eye, complete loss of vision lasts 1-2 minutes

Type II - flow related. Retinal hypoperfusion – desaturation of color, usually described as a graying of vision

Type III – vasospastic. May occur with migraines.

Type IV – miscellaneous. May occur with anticardiolipin antibodies

- b) Blindness may be permanent

2) Middle cerebral artery symptoms:

- a) Contralateral motor or sensory TIA (arm and face worse than leg)
- b) Language deficits if the dominant hemisphere involved [16, 29, 30].

INVESTIGATION OF THE EXTENT OF CAROTID ARTERY DISEASE

Despite a great deal of research on the subject, there are no data to support a particular testing algorithm. Doppler, CTA, and MRA are acceptable initial screening tests. In patients with an abnormal screening test, a common strategy is to obtain a second confirmatory noninvasive test to evaluate the carotid bifurcation before the intervention. The combination of carotid ultrasound and MRA has proved cost effective with excellent reliability. If two noninvasive tests are discordant, catheter angiography should be considered before intervention [16, 30, 31].

Duplex Doppler Ultrasound

B-mode image evaluates the artery in a cross-sectional plane, and spectrum analysis shows blood flow. Doppler ultrasound performs poorly with a “string sign” and cannot scan above the angle of the mandible. Lower frequencies give a greater depth of penetration, but the signal definition is sacrificed. Sensitivity is 88%, and specificity is 76% [18, 33, 34].

Magnetic Resonance Angiography (MRA)

MRA may obviate the need for angiography in some cases of carotid stenosis, specifically in symptomatic patients with a focal “gap” of signal intensity loss with the distal reappearance of the signal. MRA sometimes overestimates the degree of stenosis. The sensitivity of MRA is 91%, and specificity is 88% for extracranial carotid disease. 2D TOF-MRA is adequate, contrast MRA shows more but is not necessary for surgical lesions.

MRA can be performed at the time as MRI with stroke protocol in TIA/stroke patients, and also detects thrombus or dissection. As with Doppler, he has difficulties distinguishing very severe stenosis from occlusion. MRA is more expensive and time-consuming as Doppler and is more challenging to perform if the patient is critically ill, unable to lie supine, or has claustrophobia, a pacemaker or ferromagnetic implants. High-resolution MRI may also detect vulnerable plaques [18, 35-38].

Computed Tomography Angiography (CTA)

CTA involves ionizing radiation (x-rays) and IV iodinated contrast, limiting its use in patients with dye allergies and renal dysfunction. Results are comparable to MRA and Doppler. CTA can be performed within a few seconds and yields high-resolution images of

all vessels from the aortic arch through the intracranial/extracranial vessels as well as the surrounding soft tissues (Figure 3 and Figure 4). In a meta-analysis, sensitivity and specificity for detection were 85% and 93% respectively. Another potential advantage of CTA is the ability to obtain CT perfusion studies at the same time [18, 39, 40].

Figure 3. CTA: Stenosis of the ICA in the sagittal scan, marked by an arrow.

Figure 4. CTA: Occlusion of the ICA in the sagittal scan, marked by an arrow.

Angiography

The “gold standard” test is a catheter arteriogram (Figure 5). It cannot be justified as a screening test because it is invasive, and too costly and risky (recent data show under 1% risk of the transient or permanent deficit, and risk is 2-3 times higher in symptomatic patients than in asymptomatic). Also, unlike duplex Doppler and MRA, it does not provide any

information about the thickness of the plaque. Angiography also allows performing the opportunity to perform endovascular intervention if indicated [16, 18].

Figure 5. Angiography: Severe stenosis of the left ICA, marked by an arrow.

TREATMENT OF CAROTID ARTERY STENOSIS

Treatment alternatives are primarily between the following:

- 1) Medical management
- 2) Carotid endarterectomy
- 3) Endovascular techniques: combined angioplasty and stenting

Medical Management

What constitutes “best medical management” has not been precisely determined, and recommendations are always changing. Some of the following are utilized:

- 1) Antiplatelet therapy
 - a) Aspirin (ASA)
 - b) Clopidogrel, either alone or in combination with ASA
 - c) Combination of extended-release dipyridamole and ASA (no benefit from dipyridamole alone)
- 2) Antihypertensive therapy as appropriate
- 3) Proper control of diabetes if present

- 4) Patients with asymptomatic atrial fibrillation should be treated with anticoagulation
- 5) Antilipid therapy if needed – statins
- 6) Intervention to help patients to quit smoking [18, 41-43].

Carotid Endarterectomy

The literature supports significant variability in the technique of CEA. Controversy exists between a transverse or longitudinal incision, performing surgery under general or local anesthesia, intraoperative monitoring via 16-channel EEG, compressed spectral EEG, ICA stump backpressure, xenon-enhanced cerebral blood flow monitoring, transcranial Doppler, or no monitoring at all, the use of shunting during the period of occlusion, a standard longitudinal arteriotomy or the use of an eversion technique, and finally a primary arteriotomy closure or the use of autologous or prosthetic (Dacron or polytetrafluorethylene) patch closure [44, 45].

Despite the variation, no technique has been shown to have overwhelming superiority with any degree of statistical significance. It is recommended that the individual surgeon should continue with the technique with which he or she is comfortable and has established a pattern of success. Adequate morbidity and mortality data must be closely monitored; this means a 30-day overall rate of stroke and death under 3% for asymptomatic patients and 6% for symptomatic cases.

Anesthesia

Carotid endarterectomy can be performed safely under general, local, or regional anesthesia, and the General Anesthesia versus Local Anesthesia for Carotid Surgery (GALA) trial was unable to show a significant difference in outcomes between local or general anesthesia [46]. A recent review of 42,265 cases through the National Surgical Quality Improvement Program database found a significantly decreased risk of 30-day postoperative myocardial infarction in CEA performed under local or regional anesthesia when compared to CEA under general anesthesia. Although this study highlights the disproportionate number of surgeons who perform the procedure under general anesthesia (88,7%), local anesthesia has a loyal following of surgeons who argue that patient evaluation is superior to EEG monitoring during the time of cross-clamping. Harbaugh has shown excellent results in his great series of CEA patients with local or regional anesthesia. This serves as a suitable alternative in high-risk patients because it has been shown to reduce the risk of perioperative cardiopulmonary complications significantly. Furthermore, another study comparing local and general anesthesia by Wellman found a significant difference in EEG changes potentially requiring shunt placement in patients undergoing surgery while under local (6,3%) versus general (15,7%) anesthesia, although there was no difference in outcome or complications. The authors hypothesized an increased sensitivity of EEG in patients under general anesthesia as a possible etiology [14].

Surgical Procedures

Carotid endarterectomy is well established as a stroke-preventing treatment. Two distinct operative approaches are in widespread use: eversion carotid endarterectomy and

conventional carotid endarterectomy. In the 1950s, De Bakey first described the eversion carotid endarterectomy technique, a transection of the CCA just below the bifurcation with eversion of the ICA and ECA, with subsequent end-to-end reanastomosis of the CCA [47].

Conventional Carotid Endarterectomy

Carotid endarterectomy is performed by using longitudinal or oblique cervical incision, then exposure of the carotid bifurcation is obtained by division of the facial vein. Careful dissection is mandatory to avoid iatrogenic lesions of the hypoglossal, vagal and recurrent laryngeal nerve, causing dysphonia and hoarseness. Gently manipulation of the arteries (if it is necessary) should be done to prevent cerebral embolization. Usually, 2500-5000 unit of Heparin is routinely administered before clamping, and a longitudinal arteriotomy is performed from the distal CCA to the ICA as far as the end of the plaque (Figure 6). Insertion of a shunt to preserve flow depends upon the appearance of appropriate neurological symptoms when the operation is performed with the patient awake or based upon indirect evidence of insufficient collateral flow assessed by the carotid stump pressure lower than 50 mmHg (Figure 7). A 50% reduction in flow velocity detected in the middle cerebral artery by transcranial doppler if the operation is performed under general anesthesia [48].

Figure 6. Conventional endarterectomy: Arteriotomy at the CCA and ICA. Atherosclerotic plaque is visible in the inner layer of the arterial wall, without a shunt.

To remove the plaque, dissection is initiated in a subadventitial plane using the gentle dissector, and it is carried out meticulously, separating the lesion from the arterial wall. Complete removal of the lesion should always be attempted, in case that the dissection is in the correct plane the plaque goes out distally. Usually, tacking sutures of the distal intima are not necessary. Clearing of the external carotid artery ostium and its initial segment is performed routinely, and proximally, in the common carotid, the lesion is cut with scissors to avoid fragmentation and irregularities. Extreme care is taken to remove all remaining fragments of plaque and intimal flaps, which may be a source of secondary embolization or lead to secondary thrombosis [14, 48, 49].

Figure 7. Conventional endarterectomy: A shunt inserted into the CCA (left side) and ICA (right side). The shunt is marked by an arrow.

The arteriotomy is routinely closed with a Dacron patch, aiming to enlarge the artery and to prevent early recurrent restenosis secondary to proliferative fibrosis [14, 50], to correct kinking of the artery immediately distal to the endarterectomized segment and to reduce postoperative neurological morbidity (Figure 8) [51]. Clamps are released sequentially to allow an initial flush through the ECA and to prevent cerebral embolization. The vein can also be used, but there is no convincing evidence of its additional advantage over the Dacron patch [48].

Perioperative completion assessment is routinely performed with a color flow duplex scan to identify technical defects such as thrombus, floating flaps more than 2 mm or residual stenosis, which, if present, require prompt correction [52].

Figure 8. Conventional endarterectomy: Completed Dacron patch plasty of the CCA and ICA. The patch is marked by an arrow.

Monitoring with transcranial doppler is continued in the recovery room to detect brain embolization, and if there is evidence of repeated high-intensity transient signals, this could correspond to thrombus formation at the end of endarterectomized part of the artery. Administration of 250 ml Dextran 40 is performed intravenously, and usually, this is

sufficient to ensure its disappearance. However, if there is a persistence of high-intensity transient signals despite the Dextran administration, immediate cervical re-exploration is carried out, the arteriotomy opened, and thrombectomy of the carotid artery performed to prevent a significant stroke [48].

Drainage is always required, and routine closure of subcutaneous tissues and skin performed after careful inspection and perfect hemostasis.

Eversion Carotid Endarterectomy

Eversion carotid endarterectomy technique is performed under general anesthesia. The patient is placed on the operating table in the supine position with the head hyperextended and turned away from the operative side. The skin incision is made parallel to the anterior border of the sternocleidomastoid muscle. Exposure and clamping of the CCA, external carotid artery ECA and ICA are made in the usual way. Systemic heparinization is used. A right-angled bulldog clamp should control the ICA well beyond the distal end of the atheromatous plaque. The CCA is entered with a scalpel, and immediately than using scissors gently, the arteriotomy is extended in the distal direction toward the fork of the carotid bifurcation. The incision should be made precisely parallel to the axis of the ECA. Gentle scissors are then used for complete transection of the ICA (Figure 9). Transection permits complete mobilization of the artery and additional traction downward offers extra length of exposure. Endarterectomy is started at the stump of the ICA, and the plane is developed between the outermost layers of the media and the adventitia [52, 53].

The atheroma is circumferentially separated and detached while the outer layer of the vessel is everted. Fine atraumatic vascular forceps are required for these manipulations. The eversion is progressively continued to the distal part of the artery, and the atheroma is detached like a cast. Gentle traction results in complete removal of the atheromatous core, providing a slight fading and tapering endpoint (Figure 10) [52, 53].

Figure 9. Eversion endarterectomy: Transected stump of the ICA, marked by a blue arrow. A black arrow marks the CCA.

As the atheroma is removed, the luminal surface and the transition between the endarterectomized and nonendarterectomized segment of the ICA are assessed carefully. Heparinized saline is used to flood the field to remove intimal or medial debris. Flaps or

residuals are gently removed only by circumferential traction since cephalic traction can cause inadvertent intimal dissection of the ICA endpoint [52-54].

Figure 10. Eversion endarterectomy: plaque removal. The stump of the ICA after endarterectomy is marked by a blue arrow, while a black arrow marks the completely removed atherosclerotic plaque.

Figure 11. Eversion endarterectomy: The posterior wall of the anastomosis between the CCA (a black arrow) and ICA (a blue arrow) is completed.

The next step is the attempted endarterectomy of the ECA and CCA. Circumferential mobilization of the plaque is achieved by utilizing the closed jaws of a dissector. After the proximal division of the plaque, the endarterectomy is carried out into the ECA orifice as distal as possible. The arterial wall of the ICA is drawn proximal, and the reimplantation of the artery to its normal position is performed. The anastomosis begins at the bifurcation fork using a simple running 6-0 synthetic monofilament suture. The posterior wall is reconstructed first with tiny bites (Figure 11). Before the completion of the anterior wall of the anastomosis, all clamps are removed sequentially to allow back bleeding and to wash out any thrombogenic debris [52, 53].

Kiskinis recommended at this stage of the procedure dilators of appropriate size, up to 4.5 mm in diameter, may be used to dilate the extracranial segment of the ICA. Angioscopy may also be used to verify the anatomic result. Angioscopy yields an excellent visualization of the whole endarterectomized luminal surface and the endpoint of the ICA (Figure 12). After completion of the anastomosis, the blood flow is restored first to the ECA and then to the ICA. In cases with distal flaps or plaque detachment, intraoperative stent deployment may secure the distal endpoint [52].

Figure 12. Eversion anastomosis: Completed reinsertion of the ICA into the CCA. The anastomosis is marked by a blue arrow.

Many authors agreed with the advantages of the modified carotid endarterectomy technique over the open endarterectomy, especially that the longitudinal arteriotomy of the ICA is avoided and subsequently the suture line does not interfere with the lumen of the vessel. Furthermore, the use of a patch in patients with small arteries, such as women and children, is not necessary. This method is appropriate for the correction of coiling, kinking, or tortuosity of the ICA in the presence of arteriosclerotic lesions. After completion of the endarterectomy, an ICA segment of appropriate length is resected and the vessels reimplanted. On the other hand, there are some disadvantages. Among the disadvantages of eversion carotid endarterectomy is the limitation of an internal shunt placement when it is required. During the procedure of eversion endarterectomy of the ICA, only a CCA to ECA shunt can be easily used for cerebral protection. In some complex cases, when the transition endpoint of the ICA is not smooth and/or the plaque is extended distally, the replacement of

the ICA by a graft may be necessary [50, 52]. In such cases, the interposition of synthetic or saphenous vein grafts may be used [55].

Many studies have compared standard and eversion techniques for endarterectomy. The EVEREST trial compared the two methods in a randomized, prospective study published in 2000 [56]. Over a 2.5-year period, 1,353 patients were randomized to undergo eversion ($n = 678$) or standard ($n = 675$) CEA. The incidence of ipsilateral stroke was 3.3% in the eversion group and 2.2% in the standard group. There were no statistically significant differences in the rate of stroke or death between the two groups. At four years of follow-up, the cumulative restenosis risk was significantly lower in the eversion group when compared with the standard group. The most common complication after carotid endarterectomy is blood pressure instability requiring medical treatment. A recently published meta-analysis reviewed the role of surgical technique in postoperative blood pressure. The study reviewed six published reports and found that patients who underwent eversion carotid endarterectomy were more likely to develop postoperative hypertension than those in the standard carotid endarterectomy group ($P < 0.0001$), and those who underwent standard carotid endarterectomy were more likely to develop postoperative hypotension. There was no difference in the rates of myocardial infarction, stroke, death, or hematoma [57]. It may be that the increased dissection of the carotid bulb and ICA required for the eversion technique is responsible for this phenomenon. Regardless, close blood pressure monitoring in the immediate postoperative period is required, regardless of technique [52, 53].

Endovascular Techniques: Carotid Artery Angioplasty and Stenting

In recent years, endovascular treatment of carotid stenosis has been developed as an alternative to carotid endarterectomy with several potential advantages. Endovascular treatment avoids an incision in the neck with the risk of cranial or cutaneous nerve damage and potentially reduces general surgical complications, such as myocardial infarction. Surgically inaccessible lesions distant to the carotid bifurcation can be treated, and hospital stay is usually shorter than for surgery. On the other hand, endovascular treatment does not remove the atherosclerotic plaque and may dislodge thrombus or plaque material during the procedure, causing an embolic stroke. Another concern has been that residual stenosis after incomplete dilation or recurrence of carotid stenosis might limit the long-term effectiveness of endovascular treatment in preventing strokes [57].

Endovascular treatment involves the insertion of a catheter in the femoral artery at the groin under local anesthesia, which is then advanced to the site of the stenosis in the internal carotid artery. In the early years of endovascular treatment, the stenosis was dilated by inflating a balloon mounted to the catheter tip (balloon angioplasty), without routine insertion of stents. The first insertion of stents, carotid artery stenting, has since replaced balloon angioplasty as the endovascular technique of choice. Primary stenting has several advantages over balloon angioplasty: the risk of periprocedural carotid dissection is reduced, and if dissection occurs, adverse consequences such as carotid occlusion or thrombo-embolism might be minimized, because the stent maintains laminar flow across the stenosis and seals the site of dissection [57, 59, 60]. Superior dilation achieved by stenting is also likely to lower the rate of residual or recurrent stenosis compared with balloon angioplasty [58-61].

The investigators concluded that there is equipoise between carotid endarterectomy and carotid artery stenting and provided data regarding the value of anatomic features and

comorbid conditions on treatment outcomes. At the 4-year follow-up, the rates of the primary endpoint (any periprocedural stroke, myocardial infarction, or death or postprocedural ipsilateral stroke) were similar in both the carotid endarterectomy and carotid artery stenting recipients (6.8% and 7.2%, respectively; $p = 0.51$). However, during the periprocedural period (within 30 days after the procedure), a statistically significant higher rate of stroke was observed among patients undergoing carotid artery stenting than among those undergoing carotid endarterectomy (4.1% versus 2.3%; $p = 0.01$), whereas patients undergoing carotid endarterectomy had a significantly higher rate of myocardial infarction than did those undergoing carotid artery stenting (2.3% versus 1.1; $p = 0.03$). However, the overall rates of stroke, myocardial infarction, or death within the periprocedural period were similar to the two approaches (5.2% with carotid endarterectomy and carotid artery stenting 4.5% with carotid artery stenting; $P = 0.38$) [12, 13, 60-62].

Detailed analysis of periprocedural stroke events in CREST showed that when strokes occurred, they were typically ipsilateral to the treated artery and of minor clinical effect (median National Institutes of Health Stroke Scale score of 2 within 1 month) [13, 61, 63, 64]. The median time of the development of stroke was 0 days after the procedure, which suggests that these events were directly related to the procedure. In addition, the development of periprocedural stroke in association with carotid artery stenting was related to high-risk plaque characteristics, such as the presence of plaque ulcerations. Rates of restenosis, defined as in-stent stenosis of 70% or more or complete occlusion, were similar 2 years after stent placement (6.0% and 6.3%, $p = 0.58$) [12, 13, 61]. Female sex, history of diabetes, hyperlipidemia, and smoking were associated with increased risk of restenosis [61, 62].

CONCLUSION

Stroke is the second most frequent reason for death in the world and the most common reason for disability of the older population in developed countries. Symptoms of the extracranial carotid disease are most often not the result of hypoperfusion but are caused by emboli. In Europe and North America, arterial embolisms account for about a quarter of the causes of stroke, originating from atherosclerotic lesions of the carotid artery. The most common injury is a bifurcation of the carotid artery, and the microemboli result from TIA. If symptoms persist, it is a stroke or cerebrovascular accident. Embolism into the ophthalmic artery causes a temporary monocular loss of vision called amaurosis fugax or permanent blindness because the ophthalmic artery is the first branch of the ICA.

Indications for surgical or endovascular treatment are indicated: for asymptomatic patients with stenosis of internal carotid artery more than 70% or symptomatic patients with stenosis of internal carotid artery more than 50%. Symptomatic patients are those that had a stroke or TIA within 180 days. Asymptomatic patients are those that had stroke or TIA before more than 180 days or those that did not have any stroke or TIA.

Contraindications of treatment are occlusion of the internal carotid artery. Surgically it is possible to do revascularization of carotid occlusion. However, there is a high risk of fatal bleeding in the ischemic area of the brain after such revascularization. Hence revascularization of occlusion of the internal carotid artery is contraindicated. The only exception is the interval within the first 6 hours after occlusion. Only within this interval,

acute occlusion of the carotid artery can be operated. Another contraindication is unstable neurological finding, stroke in evolution. Revascularization of a neurologically unstable patient could also lead to intracerebral bleeding. Patients with expected live survival less than two years and patients in generally bad status are contraindicated for treatment too.

Carotid angioplasty and stenting are an alternative method of carotid revascularization. Carotid stenting has a higher risk of embolization and stroke compared to carotid endarterectomy. Therefore, carotid stenting is indicated only in patients with a high risk of the operation. High-risk patients are those with severe cardiac or pulmonary disease, who are after neck radiotherapy or who have had carotid endarterectomy previously. Early studies of carotid angioplasty and stenting have shown promise with similar morbidity and mortality rates to carotid endarterectomy, but later studies showed a higher risk of stroke by carotid stenting and higher risk of myocardial infarct by carotid endarterectomy. Carotid stenting has already become the primary treatment option for occlusive lesions of the origins of the arch and recurrent stenosis after treatment.

**PERIPHERAL ARTERIAL DISEASE:
UPPER EXTREMITY ARTERY DISEASE,
LOWER EXTREMITY ARTERY DISEASE,
ACUTE LIMB ISCHEMIA**

Mária Kubíková*, MD, PhD

ABSTRACT

Lower limb ischemia is a serious problem that affects the health and quality of life of 2-5% of the population in industrialized countries. Lower limb ischemic disease is one of the most severe diseases that vascular specialists encounter.

With the growing age of the population in industrialized countries, it also poses a significant health problem (it is the most common vascular disease in the population).

Patients with PAD are in high-risk of cerebrovascular and cardiovascular complications. Proper management and assessment of the overall condition with determining the most appropriate treatment are important for disease prognosis. In the healthcare centers, it is recommended to set up a multidisciplinary Vascular team to make decisions for the management of patients with PADs [40].

Access to these patients involves early detection of risk factors, elimination of known existing risk factors (smoking cessation, healthy diet, and physical activity) and the proper treatment of diseases such as diabetes and hypertension. Long-term antiplatelet therapy is also essential. In most patients, conservative treatment is sufficient. Interventions are only indicated in case of severe limiting claudication or critical ischemia when a limb is at risk. The first interventional trial in patients with a suitable lesion is endovascular treatment - PTA and additional methods for their low complications and less invasiveness. Interventional therapy may be endovascular or classical open surgery or a combination of both. Bypass surgery when using autologous VSM remains the gold standard. Primary amputation has a diminishing role in the treatment of CLI with an expansion of endovascular techniques [50].

Optimal management of acute lower limb ischemia is based on the severity of the ischemia at presentation.

Upper extremity vascular disorders are less common compared to lower-extremity vascular disease and are rare in comparison to those involving the lower extremities. Upper extremity arterial disease evaluation, diagnosis, and treatment represent a much different spectrum than those of lower extremities. The management is difficult and requires an assessment of vascular structure and function. Upper extremity vascular disease due to atherosclerosis is mostly situated at the level of the brachiocephalic trunk and the subclavian and axillary arteries. In most asymptomatic patients, medical treatment is the option of choice. When revascularization is considered, both endovascular and open surgical options can be proposed, according to lesion characteristics and the patient's risk [40].

Wifi	wound, ischemia and foot infection

INTRODUCTION

Lower limb ischemia is a serious problem that affects the health and quality of life of 2-5% of the population in industrialized countries. Lower limb ischemic disease is one of the most severe diseases that vascular specialists encounter.

The title “peripheral arterial (occlusive) disease” (PAD) for diseases of peripheral arteries is used in the world literature [1] and means especially lower extremities.

With the growing age of the population in industrialized countries, it also poses a significant health problem (it is the most common vascular disease in the population).

Not only is the lower limb disease itself dangerous, but the atherosclerosis (AS) of the lower extremities is also a marker of systemic AS disease, especially cardiovascular and cerebrovascular disease.

The prognosis of these diseases is the same, with the mortality rate about 30% within five years, while in patients with critical limb ischemia, the five-year mortality is 50% [2].

The most severe consequence of PAD is severe limb ischemia, which is characterized by intolerable claudication, resting distal pain, skin ulcerations and trophic defects up to gangrene, which leads to amputation without adequate treatment.

Amputation is a serious handicap for the majority of people because it limits their daily activities, and in most cases, the sick person is dependent on the permanent care of another person.

DEFINITION

The most commonly used definition for PAD is a resting index (ABPI-“ankle-brachial” index) of less than 0.9 [3, 4]. Patients may be clinically asymptomatic, may have intermittent claudication (IC) - is a symptom of muscular lower limb pain brought by exertion and relieved by rest or may have chronic critical limb ischemia (CLI) with night pain, rest pain, tissue loss.

EPIDEMIOLOGY OF PAD

The incidence (the rate of new cases of the disease) and prevalence (the actual number of cases alive with the disease) of PAD increases with age. For 60 and more years, it is estimated at 10-30%. The incidence of lower limb ischemia in diabetic patients is four times higher than in the general population and increases with increasing age [5].

The actual incidence of CLI is difficult to estimate, but based on the number of amputations, the prevalence of 500-1000 per million inhabitants [6] is estimated, although this is probably underestimated. In a group of 20,000 patients aged 40-69 years, the reported CLI of 0.24%, similar in both sexes, which increased with age and the presence of risk factors [7]

Disease progression: 20% of PAD patients look for a doctor, while another 20% have difficulties but do not pay attention to them. In 75% of men, claudication never causes a serious problem. Intermittent claudications progress to rest pain or gangrene in 15-20% of patients [8].

NATURAL HISTORY OF PAD

It is different in asymptomatic patients and patients with claudication and those with CLI. Patients with asymptomatic PAD and IC have the same increased risk of developing myocardial infarction (MI) and stroke [3]. The mortality for s IC is about 30-42% /40-65% in 5/10 years, with the risk of amputation being less than 5%.

CLI mortality is up to 25% per year and 50% after five years [2, 9] mainly due to cardiovascular 55% and 10% in cerebrovascular diseases. The risk of amputation per year is up to 35% [10]. The risk of limb loss increases if the patient continues to smoke.

HISTORY

The first vascular reconstruction was carried out by the English surgeon Hallowell in 1759 when he treated brachial artery injury with a wall suture.

Ambroise Paré is considered the founder of modern amputation surgery. At the beginning of 16th century, he used a ligature to stop bleeding in amputated limbs after injury for the first time.

Alexis Carrel is considered the father of vascular and transplant surgery. Carrel also developed today's basic vascular surgery procedures. He was awarded the Nobel Prize for Medicine for his extensive work in 1912.

New advances in anesthesia, blood transfusion, the discovery of new antibiotics, heparin in clinical practice, the introduction of angiography and special sewing materials (all this after World War II) contributed to the rapid development of vascular surgery. While at this time, the main drawback of growth was the lack of a suitable vascular replacement, there are now many ways to replace, eventually, reconstruct damaged or obliterated vessels. The first femoral endarterectomy was performed in 1947 by Dos Santos. Dubost did the first resection of ruptured aneurysm of abdominal aorta and replacement by allograft in Paris in 1952. The first resection of carotid bifurcation for prevention of recurrent cerebral ischemia was carried out by Eastcott in London in 1954.

The fast development of vascular surgery brought the introduction of prosthetic grafts by Vorhees in 1952. That enabled De Backey to resect abdominal aortic aneurysm and replace it with synthetic graft in 1955. Seldinger performed the first angiography with a catheter in 1952. Dotter and Judkins first described percutaneous transluminal angioplasty (PTA) in 1964 that used a coaxial catheter. Gruntzig in 1974 was the first who did PTA and started the modern era of endovascular treatment [11].

Over the past 30 years, the care for patients with vascular diseases has changed significantly. Vascular medicine, which uses invasive diagnostics and therapeutic methods, has now gone into a period of less invasive diagnosis and treatment, represented by ultrasound (USG) methods, endoscopy, and invasive radiology. Revolutionary changes are appearing in vascular surgery all the time. Duplex ultrasonography (DUS) and less invasive radiology - computed tomography angiography (CTA), magnetic resonance angiography (MRA), three-dimensional ultrasound visualization and three-dimensional MRAs allow a more detailed view of the arterial bed, refine diagnosis and contribute to less discomfort and morbidity [12].

The consequence of the rapid development and improvement of endovascular techniques is that open surgical interventions are progressively replaced by technologies that use catheters, balloons, balloons, and stents coated with drugs and stent grafts. The methods are used alone or in combination with one or more surgical procedures.

An essential part of the rapid development is the improvement of MRA with the refinement of hardware and software and non-nephrotoxic contrast-media. Smart communication technology makes medical education and communication much faster and more accessible.

ETIOLOGY

The most common cause of PAD is atherosclerosis (AS) in 90%. AS is a generalized disease that affects the arterial system, especially the lower extremities.

Complex genetic and environmental interactions lead to structural and functional abnormalities and reduction of blood flow.

Nonatherosclerotic disorders causing lower limb ischemia are: primary and secondary vasculitis (Takayashu Morbus, Kawasaki Morbus, Buerger's Morbus, postirradiation arteritis,

vasculitis in rheumatoid arthritis). Vasoneuroses and fibromuscular dysplasia are less common. More often, we encounter the consequences of metabolic disorders in diabetes mellitus [9].

The peripheral arterial disease can exceptionally be caused by persistent sciatic artery, cystic degeneration, popliteal artery entrapment syndrome, tumors, and others.

RISK FACTORS FOR PAD

PAD is one of the most severe clinical manifestations of atherosclerosis. There are several risk factors associated with disease progression.

- a) non-modifiable: age, gender, and ethnicity
- b) modifiable: cigarette smoking (risk increased four fold), diabetes mellitus (two-fold), hypertension (2,5-4 fold), hypercholesterolemia, chronic renal failure, high fibrinogen level, CRP(C-reactive protein), (patients with elevated CRP are at higher risk of postoperative cardiovascular events) [13]).

ETHIOPATOGENESIS

Atherosclerosis is a capital global problem with high cardiovascular mortality. The clinical picture depends on the organ involvement, the intensity, the duration of action of atherosclerosis, and the associated diseases. A combination of risk factors increases the risk of atherosclerosis 16 times as much as one risk factor. According to Rose's theory, inflammation and endothelial dysfunction with lipid accumulation play a significant role in atherosclerosis. Inflammation is either a defensive or damaging reaction. Atherosclerosis is now considered a chronic inflammation [14]. Inflammation plays a critical role in atherosclerosis and the development of a vulnerable plaque [15]. AS is manifested either by dilation or stenosis with arterial occlusion.

Artery narrowing and occlusion: The arteries of the human body are dimensioned to have the ability to increase the flow rate several times with a corresponding decrease in peripheral resistance. Reducing the area of the lumen must reach about 75% (corresponding to a 50% reduction in diameter). So that the constriction becomes apparent in rest conditions. Tissues and organs whose flow rate increases significantly as a result of a decrease in peripheral resistance are sensitive to smaller restrictions in such a situation. At the constriction site, the laminar flow changes to turbulent, resulting in blood particle deposition and fibrin apposition, endothelial deterioration, and breakdown. Thus, the progression of the constriction is further promoted to ultimately the complete closure of the remaining lumen by thrombus

Compensation mechanisms: the metabolic compensation is created thanks to the decrease of resistance in muscles, developing of collaterals, and increasing the oxygen extraction. The clinical picture emerges depending on the location of the narrowing and the rate of closure. The principal compensation mechanism for significant stenosis is collateral circulation. The slower the progression of the obliterating process, and the less the disease process is affecting the river that serves the collateral circulation, the better the development of the collateral

circulation. Under certain favorable circumstances, it can entirely or largely compensate the arterial closure. Collateral develops more in the proximal sections while parallel arteries also dilate. Atherosclerosis preferentially involves the distances of the arteries and their branching. That's why we talk about its segmental character.

Aneurysms: The aneurysm is when a specific section of an artery is significantly expanded from that adjacent to an otherwise normally large artery. Aneurysms are divided by shape and etiology. We divide them into the right (all the layers of the vascular wall form the aneurysm wall), and the false ones (the wall consists of only one layer of the vascular wall, or just surrounding scar tissue). The arterial aneurysm is always a progressive disease and threatens the patient with rupture, with subsequent bleeding, compression of surrounding structures, peripheral embolism but also thrombosis.

Critical limb ischemia (CLI): develops when arterial lesions reduce blood flow to such an extent that it is unable to supply the nutritional requirements of tissues. This situation is most common in multisegmental artery disease. In some cases, the hemodynamic parameters of arterial lesions are multiplied by chronic venous insufficiency or by a decrease in cardiac output. Patients with severe peripheral arterial occlusion of lower extremities have impaired microcirculation resulting from decreased perfusion pressure, which may lead to continuous ischemic pain and or tissue loss [16]. In addition to the reduction of total blood flow, the CLI also has a maldistribution of cutaneous microcirculation [3, 6]. Saving the cutaneous microcirculation is essential for a good prognosis. Thus, after successful revascularization, the determinant factor is not only the recovery of the macrocirculation but also microcirculation, which is essential for skin nutrition and must be taken into account. After restoring the blood circulation, another clinical condition arises - reperfusion with consequences both local and systemic. These two conditions are closely related therefore the term ischemic-reperfusion syndrome is appropriate [17].

Definition of Critical Limb Ischemia

The term critical limb ischemia describes the condition, where the function and vitality of extremities are compromised due to decreased perfusion. During arduous and risky treatment, not only the limb itself, but also the patient's life is endangered. If the extremity is not saved and the patient survives, the quality of his life is significantly affected.

Based on the time factor in the emergence of limb threat, we distinguish two types of critical limb ischemia: acute and chronic.

ACUTE LIMB ISCHEMIA

It is the result of occlusion of a native artery or vascular/endovascular prosthesis. Emerges suddenly from acute occlusion of the artery in connection with significant tissue congestion. The sudden closure of the previously unchanged artery is due to embolism when 80% of the emboli is of cardiac origin [18, 19]. In situ thrombosis in a native artery is now the commonest cause of acute limb ischemia (ALI). It may be the result of rupture of an atherosclerotic plaque or critical flow arrest at the site of an atherosclerotic stenosis), others

causes are: aortic dissection or embolization, surgery, heart failure, thrombotic tendency, popliteal aneurysm, bypass grafts, endovascular treatment, iatrogenic, traumatic, phlegmasia coerulea dolens, ergotism [20].

The revised (2007) Transatlantic Inter-Society Consensus [3] defines acute leg ischemia (ALI) as any sudden decrease in limb perfusion, causing a potential threat to limb viability.

As collateral circulation is not developed, there is a risk of irreversible damage to the limb in a very short time. The treatment of these diseases is always urgent and immediate [17]. Treatment consists of restoring blood flow and tissue perfusion as quickly as possible. An essential therapeutic effort in acute lower limb ischemia is the rapid removal of the occlusion or the solution by intervention or surgical treatment. The main symptoms of acute occlusion of the limb arteries are intense pain, pale, waxy appearance, cold, loss of sensitivity, no pulse distal to occlusion, sudden limb weakness, positive Ratschow positional test [21].

MANAGEMENT OF ACUTE LOWER LIMB ISCHEMIA

Classification of acute limb ischemia is based on the severity of arterial ischemia, which helps determine the urgency of intervention and has implications for the outcome. The categories are based on clinical findings and Doppler measurements. Patients are grouped into the following categories [20]:

- I Viable
- IIa Threatened (salvageable if promptly treated)
- IIb Threatened (salvageable if immediately treated)
- III Irreversible

Table 1. Clinical categories of acute limb ischemia [24]

Grade	Category	Sensory loss	Motor deficit	Prognosis
I	Viable	None	None	No immediate threat
IIA	Marginally threatened	None or minimal (toes)	None	Salvageable if promptly treated
IIB	Immediately threatened	More than toes	Mild/moderate	Salvageable if promptly revascularized
III	Irreversible	Profound, anaesthetic	Profound, paralysis (rigor)	Major tissue loss, permanent nerve damage inevitable

Clinical presentation: the symptoms depend on the size of artery occluded and whether collaterals have developed beforehand. Complete occlusion of a proximal artery in the absence of performed collateral vessels results in the classical clinical presentation of pain, pallor, pulselessness, paresthesia, paralysis, and cold leg. If the flow is not restored rapidly, irreversible ischemia develops after 6-12 hours.

When an arterial occlusion occurs as part of a chronic process in the presence of well-established collaterals, the leg is less severely ischemic.

Initial management: the anatomical location of the arterial occlusion can be diagnosed. Patients presenting with ALI are often in poor general health. Dehydration with catheter monitoring of urine output, hypoxia, cardiac failure, and pain all are managed, venous blood should be taken for full blood count, glucose, urea and electrolytes, electrocardiogram (ECG) and cardiologic assessment. An initial bolus of intravenous calcium heparin 5000U is appropriate for most patients, and analgesics should be given as soon as possible.

Class I ischemia: (viable) intervention may be risky, and there is an argument for conservative treatment. In class II ischemia, requires intervention, in IIa (marginally threatened), there is time for investigation and semielective intervention. IIb (immediately threatened with pain at rest, sensory loss and muscle weakness) - the acute leg with sensorimotor deficit requires urgent intervention. Any delay in treating risks limb loss. In class III or irreversible ischemia, there is no indication to revascularization.

Upper limb ischemia: Arm ischemia is seldom limb threatening, and most arm ischemia is due to embolism. An only small number of patients present with class II b critical ischemia and should undergo urgent surgical intervention [22].

Medical therapy: anticoagulation, hydration, analgesia, improving oxygenation.

Endovascular treatment: catheter-directed thrombolysis - thrombolytic agents dissolve the occluding arterial thrombus, the percutaneous mechanical thrombectomy-the procedure is performed in the angiography suite and can remove thrombus from the arteries. They may be classified according to their mode of action (hydrodynamic, aspiration, fragmentation, rotation and aspiration).

Surgical treatment: balloon catheter embolectomy introduced by Fogarty, completion angiogram should always be performed in evaluating the completeness of thrombus removal. After failed open balloon thrombectomy bypass procedures are available. Endarterectomy is most commonly performed for in situ occlusion of the common femoral artery.

In lower extremity to prevent a post-reperfusion compartment syndrome extremity, four-compartment fasciotomies should be performed in patients with long-lasting ischemia.

Complications: Multiple organ dysfunction, acute renal failure due to myoglobinuria, compartment syndrome – a patient should be monitored for any signs of compartment syndrome.

Figure 1. Embolisation of left lower extremity- popliteal artery (category II b).

Figure 2a. The left lower extremity after embolectomy.

Figure 2b. The left lower extremity after embolectomy.

CHRONIC LIMB ISCHEMIA

The chronic form of critical lower limb ischemia develops gradually (months and years), and the potential for the development of collateral circulation plays an important role in its development. This form is characterized by multisegmental involvement of the arterial bed, practically always with the involvement of significant damage to the leg and leg arteries.

Severity of PAD is commonly reported by two classification systems.

The most common is the original classification of leg limb ischemia according to Fontaine and Rutherford [23], both of which are equally valid. The simplest is the original Fontaine classification, it is based on clinical symptoms and consists of a four stages: 1st stage - latent stage: it is free of subjective manifestations, but the basic and functional angiological examinations detect objective signs of AS. 2nd stage - claudication stage (IC) manifested by spasmodic pain developing on walking in the muscle groups distal to the arterial obstruction and the symptoms relief within 5-10 minutes of cessation of exercise. The second stage may be further subdivided into stages II.A and II.B and II.C, for which the characteristic absolute claudication distance (ACD) is greater than 200 m (A); or less than 200 m (B); and less than 50 m (C). (Table 1). Stage III is defined as the presence of rest pain:

III.A - rest pain in a horizontal position that recedes when the limb hangs and III.B – constant pain in feet. Stage IV represents ischemic lesions such as ulceration or gangrene. In practice stage III. And IV. according to Fontaine corresponds to the WHO definition of CLI. Like the definition, Fontain's classification is not reliable in diabetics.

The Rutherford classification [24] of the severity of PAD can be considered a more modern version of the Fontaine scheme: it was formulated 43 years later and is based on new knowledge of epidemiology and pathophysiology, the possibility of revascularization as well as clinical outcomes. Rutherford's classification divides lower limb artery disease PAD into 3 degrees and six categories (Table 2).

Table 2. Classification of peripheral arterial disease. Stages according to Fontaine, and categories according to Rutherford (TASC II, 2007)

Fontaine		Ruhterford		
Stage	Clinic	Degree	Category	Clinic
I	Asymptomatic	0	0	Asymptomatic
IIa	Mild claudications	I	1	Mild claudications
IIb	Moderate to severe claudications	I	2	Moderate to severe Claudications
		I	3	Severe claudications
III	Ischaemic rest pain	II	4	ischaemic rest pain
IV	Ulcerations or gangrene	III	5	small loss of tissue
		III	6	Extensive tissue loss

The European Consensus defines (chronic) critical limb ischemia as rest pain for more than two weeks, and/or ulceration/gangrene, and an ankle pressure of < 50 mm Hg or a toe pressure of < 30 mm Hg (9) [6].

According to the recommendations of the TASC II Working Group [3], the clinical definition of critical limb ischemia is as follows:

(Recommendation 16) - The term critical limb ischemia should be used for all patients with chronic ischemic rest pain, ulcers or gangrene, attributable to objectively proven arterial occlusive disease. CLI is chronic and must be distinguished from acute limb ischemia.

CLI patients are at high risk. The risk of developing myocardial infarction (MI), stroke, and vascular death is three times higher in patients with CLI than in patients with intermittent claudication [25]. 40% of patients have symptoms from coronary artery stenosis, 10-15% have symptoms related to carotid artery stenosis, and 30-40% are treated for hypertension. About 50% of patients die within five years of the onset of vascular symptoms [3], due to MI and stroke [26]. Atherosclerosis is a systemic disease that simultaneously affects several vascular regions. Therefore, it is essential to examine the patient with CLI comprehensively.

DIAGNOSIS

Correct diagnosis and assessment of the results of individual examinations co-determine the efficacy of therapy [27]. The diagnostic and therapeutic assessment aims to save the limb, improve the quality of life of the patient, and reduce the morbidity and the mortality.

History taking and physical examination of the arterial system plays a very important role.

History taking: claudication pain - typical pain (ache, cramp, tightening) developing on walking that forces the patient to slow down or stop, with a relief of symptoms within a few minutes, feeling cold in the limb, tingling, permanent rest pain. The patient must be asked about the history of ischemic heart disease and cerebrovascular disease.

Physical Examination

- a) Inspection: color variations of skin, specifically cyanosis and pallor, hair growth, condition of the toenails, atrophic skin and muscles, skin ulcerations (their base, their borders).
- b) Palpation: is used to detect peripheral arterial pulsations, evaluation for edema, vibrations, and extremity surface temperature.
- c) Auscultation: assessments of peripheral arterial bruits and pathologic venous hums.

Exercise challenge: examination the extremity following an exercise challenge (Prusik, Ratschow, Allen's test)

ABPI (ankle-brachial pressure index) measurement: is measured by using a tourniquet and insonating the pedal arteries with Doppler ultrasound. The systolic blood pressure is taken from the brachial artery and from the pedal arteries. ABPI is calculated as the ratio of the ankle to the systolic brachial pressures. The characteristic cut-off point for the peripheral arterial disease is less than 0.9 in rest (normal 1,0-1,2) [1].

Blood pressure taken from the pedal and digital arteries is an important tool of estimating treatment outcomes. ABPI should be a routine part of vascular examination [3].

Risk factors: all patient should be investigated for risk factors for AS-all require a full blood count, erythrocyte sedimentation rate, urea, electrolytes, blood glucose, and lipid levels.

Vascular laboratory: the aim is focusing on and revealing the etiology of the disease. The special investigation methods should include both macro and microcirculation examinations. In patients with diabetic foot, a thorough neurological examination (pain, temperature, skin touch and vibration sensitivity, reflexes) is also required.

Nonvasive and Invasive Investigations

1. The use of Doppler waveforms originally implemented using hand-held continuous-wave Doppler devices - ABPI ratio must be correlated with analysis of the Doppler arterial wave-forms used to obtained pressures. Normal arterials waveforms demonstrate a tri-or bi-phasic pattern.

2. Duplex ultrasound (Figure 3a,b) is a non-invasive imaging study, and for its wide availability is considered to be the first line examination method. This technology combines the evaluation of blood flow (pulsed Doppler spectral analysis) and anatomic (B-mode and color Doppler imaging) information. We can collect the morphological image of arteries and veins by ultrasound. Ultrasound is able to recognize aneurysms and false aneurysm. Using the Doppler effect, we can obtain information about the arterial and venous flow. Doppler can

distinguish between normal, reduced, or abnormal flow. The reliability of arterial duplex testing depends on factors that include the expertise of the examiner and the knowledge and experience of the interpreting physician. Testing performed in an accredited vascular laboratory has sufficient diagnostic accuracy for clinicians and often avoid performing more invasive, expensive diagnostic testing, such as computed tomography, magnetic resonance imaging or angiography [11, 28].

Figure 3a Duplex ultrasound [11].

Figure 3b. Duplex ultrasound [11].

- Radiological investigations (if an invasive or operative solution is assumed).

3. Magnetic resonance angiography (MRA): is performed by applying an external magnetic field, gradients, and an oscillating magnetic field, the radiofrequency field. The combination of these three types of large magnetic fields enables to produce a visualization of the human's body, known as MR images. It is based on MRI with using paramagnetic contrast medium that is applied intravenously. Its advantage compared to CT-angiography is that contrast medium used by MRA is not based on iodine and can be used by iodine allergies and in renal insufficiency. The other advantage of MRA over CT-angiography is better quantification of calcified lesions. Disadvantages of MRA are worse availability and higher price compared to CT-angiography. Moreover, CT-angiography is quicker than MRA. Important is also the fact that patients cannot use MRA with pacemakers and metallic implants.

4. Computed tomography (CT): is also a minimally invasive imaging study. Visualization of vessels on CT is limited by the similar densities of blood and soft tissue. Administration of intravenous contrast medium can solve this problem-computed tomographic angiography (CTA), 50-130ml of intravenous contrast is applied. Rapid scanning enables visualization of the vessels during the short period that a bolus of contrast medium passes the imaged volume. Thus faster times and increased numbers of detectors allow a larger part of the body to be imaged as the bolus of contrast medium passes (Figure 4). Data obtained by computed tomography angiography make possible 3-dimensional reconstruction of the arterial system, so-called Volume Rendering Technique (VRT). 2D reconstructions MPR (Multi Planar Reconstruction) enable to make scan in any section of the examined tissue. This is important for planning of operation of aneurysms and false aneurysms. Timing of the initiation of image acquisition relative to the injection of the contrast medium is very important for maximizing visualization of vessels in the scanned volume. CTA is used for planning of vascular reconstruction in thoracic, aortoiliac, femoral and supraaortal region. CTA has its limitations, especially in imaging of popliteal, crural arteries and also arteries of upper extremities. CTA is not very precise in the quantification of strongly calcified lesions. Advantage of CTA over other imaging methods is its very good availability [11].

The UK National Clinical Guideline Lower Limb Peripheral Artery disease: diagnosis and management, recommends CT angiography to people with a peripheral arterial disease who need further imaging prior to revascularisation (after duplex ultrasound), if CE-MRA is contraindicated or no-tolerated [29].

Figure 4. Computed tomography with contrast medium.

5. Angiography: Digital subtraction angiography (DSA) is often referred to as the gold standard in the investigation of PAD. Contrast angiography is one of the most important imaging studies in vascular surgery. Contrast medium is applied directly to the arterial system, usually via a catheter in the right common femoral artery. Patients with stenoses or occlusions in the aortoiliac region have angiography performed through the radial or brachial artery. Advantage of this method is that DSA most precisely identifies the anatomy of arterial occlusive disease (Figure 5, 6). Angiography is crucial for planning of infrainguinal arterial reconstructions and also for imaging of arteries of upper extremities. A disadvantage of the method is using of iodine contrast medium, which can lead to an allergic reaction or can worsen renal functions. The other disadvantage of angiography is its invasivity. Severe bleeding from the femoral artery that requires surgical intervention is about 1%. Thus DSA is

now reserved for situations, where here is an intention to proceed to endovascular intervention and is not used as a first line image method nowadays.

Figure 5. Angiogram - an occlusion of superficial femoral artery with the development of collateral circulation.

Figure 6. Angiogram - an occlusion of both superficial femoral arteries.

6. Carbon dioxide (CO₂) angiography: The use of CO₂ is not associated with nephrotoxicity and allergic reactions. However, caution needs to be exercised in the use of CO₂ in situations where there is a risk of gas trapping and ischemia (mesenteric, carotid angiography) [30].

7. Intravascular ultrasound (IVUS) Intravascular ultrasonography is an invasive examination that mediates a detailed intraarterial image. It can alert to wall dissection, and no contrast and radiation are needed.

8. Angioscopy allows visualizing the interior of the vessel accurately. The usage is mainly in some therapeutic procedures (valvulotomy, embolectomy, thrombectomy, endarterectomy).

9. Other investigation methods: Determination of the claudication interval (distance walked by the patient without claudication). Treadmill exercise testing is used to provide objective evidence of the patient's walking capacity. Oscillography, plethysmography, Doppler ultrasound wave analysis, segmental pressure analysis [31]. Microcirculation

investigation: the investigation of the nutritional status of the skin. It is a videocapillaroscopy, measuring tissue oxygen partial pressure by transcutaneous oximetry (TcPO₂). Laser Doppler flowmetry studies skin perfusion to a depth of 1 mm and measures both nutritional and thermoregulatory blood flow. Fluorescent videomicroscopy is also possible.

MANAGEMENT OF CHRONIC CRITICAL LOWER LIMB ISCHEMIA

Routine examinations: Doppler examinations of supraaortic branches, USG of the abdominal aorta, ECG and chest X-ray, if needed. Examination of blood count, platelet count, urea, electrolytes, glucose, CRP, haemocoagulation status [32], cholesterol, triglycerides, respiratory and renal function are important. Based on these findings, an exact internal examination is needed.

Complementary examinations are: exercise ECG, ventilometry, echocardiography, radionuclide ventriculography, Holter monitoring, cardiac catheterization, and coronary angiography are also indicated if necessary. Patients with a history of venous thrombosis or recurrent arterial occlusion should be screened to exclude thrombophilic status (C, S, AT III, lupus anticoagulant, anticardiolipin). The X-ray of the bones is obligatory in the case of a defect or ulceration to exclude osteomyelitis or diabetic neuroarthropathies. For defects in the lower extremities, microbiological examination and targeted antibiotic therapy of infected defects is required. Inflammatory biomarker levels correlate with the severity of PAO and the clinical presentation of the disease in patients with infrainguinal bypasses. Patients with elevated CRP are at higher risk of postoperative cardiovascular events [13].

Macrocirculation examination: continuous Doppler (CWD) is available for the flow examination, duplex ultrasonography currently under certain conditions may also be an alternative to angiographic examination and may decide on the indication for revascularization in the case of CLI [28]. In CLI, duplex ultrasonography allows for the examination of arteries that are not shown in angiography, also allows for VSM examination and mapping of its quality and progression, whether it is suitable for autogenous bypass. Furthermore, it is oscillography which in diabetic patients only has a 10% utility for mediocalcinosis. The basic diagnostic examination method for PAD is the measurement of systolic pressure in the ankle area by Doppler ultrasound meter. We consider not only the absolute pressure values on both lower extremities but also the ankle-brachial pressure index (ABPI), which is the ratio between the systolic pressure measured on the ankle and the shoulder [1]. The ankle pressure is measured using a Doppler probe which is attached to ADP or ATP. The manometer cuff is loaded on the tibia. We then compare the systolic pressure on the shoulder and the ankle and determine the ABPI. Measurements are taken over the patient's 20 minutes rest period. Normal values are 0.9-1.2; more than 1.2 indicates mediocalcinosis; 0.9-0.5 is mostly in claudication, an index of less than 0.5 indicates critical limb ischemia.

In the rigidity of the artery wall, especially in diabetics, it is recommended to measure peripheral pressure on toes. Here, the measured pressure of less than 30 mmHg is in severe ischemia. We continue to determine profundapopliteal collateral index-PPCI [33], in diabetic patients with incompressible vessels, a "pole test" where the hydrostatic pressure is measured when the limb is elevated [34, 35]. If we choose arterial intervention (reconstruction or percutaneous transluminal angioplasty (PTA), digital subtraction angiography of the

abdominal aorta with renal vessels and limb angiography is also needed to visualize the run-off vessels. DSA angiography remains the gold standard, especially if revascularization is planned and simultaneous endovascular performance is preferred [36]. With the development of technology and refinement of less invasive but accurate imaging methods in post-ultrasonography diagnostics, MRA, and CTA (high-quality instrumentation and staffing, ambulatory examinations) are preferred [29]. MR angiography can avoid the use of contrast media but has its drawbacks and interpretation depends on software and the subjective factor of the evaluator. In addition to severe renal insufficiency, the administration of gadolinium is relatively contraindicated due to the possibility of nephrogenic systemic fibrosis. Intravascular ultrasonography is an invasive examination that mediates a detailed intraarterial image. Angioscopy allows accurately to visualize the interior of the vessel. It is mainly used in some therapeutic procedures (valvulotomy, embolectomy, thrombectomy, endarterectomy).

TREATMENT FOR SYMPTOMATIC PAD

Medical Treatment for Symptomatic PAD

PAD is a common disease, and patients with PAD have limited mobility and quality of life. In addition, PAD is a significant marker of cardiovascular (CVS) risk. PAD patients are six times more at risk of cardiac death, and asymptomatic patients are at risk too. Especially in asymptomatic patients and IC patients, appropriate treatment is underestimated. The main goal of PAD treatment is to reduce CVS risk and improve symptoms of the disease. Risk factors need to be treated and corrected. Smoking cessation, increased physical activity, as well as anti-aggregation treatment, reduction of obesity leads to a significant reduction in CVS morbidity and mortality. Unfortunately, a large proportion of patients are not adequately treated [4, 32]. Statins and antiplatelet therapy reduce IM, stroke by 23% in PAD [3, 37, 38].

The treatment strategy for PAD is described in the International Guidelines [38, 39, 40]. Exercise therapy is most effective in terms of the long-term improvement of the claudication interval, as well as the cost of treatment [41]. It also reduces cardiovascular mortality. Few vascular patients have access to these programs. Mazari et al. [42], found that the combination of endovascular revascularization with interval walk reduced the number of re-interventions as well as the cost of treatment.

Pharmacologic therapy: vasoactive drugs are the choice: Cilostazol is indicated for PAD without pain at rest, without defects. It has antithrombotic activity, inhibits platelet activation and aggregation, has vasodilator properties, affects triacylglycerol and HDL cholesterol concentrations. There is evidence, that it prolongs the claudication distance to twice the placebo and the effect of pentoxifylline. Naftidrofuryl oxalate also prolongs the claudication interval. Pentoxifyllin extends the claudication interval by 12%, according to AHA recommendations [38], 3x400mg is recommended as an alternative therapy to Cilostazol, to prolong the claudication interval in patients with IC (level of evidence A). Sulodexide is effective in the treatment and/or prevention of PAD. It protects the endothelium, has an antithrombotic and antiproliferative effect, has a rheological effect as confirmed by the SUAVIS (arterial arm) study, extending significantly painless and maximum claudication

distance [43]. At the same time, the incidence of serious cardiovascular adverse events was more than 2-fold lower in the Sulodexide group compared to placebo.

Antiplatelet and antithrombotic medications: antiplatelet drugs reduce the risk of vascular death, IM, and stroke by approximately 25% in PAD patients. Single antiplatelet therapy is recommended in symptomatic patients [40].

The effect of L-Arginine, carnitine, Ginko Biloba, E vitamin, and chelates in IC is questionable. Prostaglandin E1 and prostacyclin are indicated in CLI. They reduce pain and improve defect healing but are limited to a small percentage of patients, thromboembolism prophylaxis [44], systemic antibiotic therapy, thrombolytic therapy (urokinase, streptokinase, rTPA), hemodilution (if hematocrit is increased even with good patient hydration), pain treatment.

Therapeutic angiogenesis and cell therapy are possible - only small patient populations are available.

Risk Factor Identification and Modification (Total and Local)

Smoking is the most serious risk factor in the development of PAD, and the association between smoking and CLI is well known [2, 45].

Diabetic patients have two to four times the rate of PAD compared to nondiabetic patients and are more likely to have infrapopliteal PAD than nondiabetic subjects [46]. As with non-diabetics, PAD progression is also more rapid in diabetics. Diabetes is an independent risk factor for postoperative complications and amputations [47]. Chronic management should lower the level of glycated hemoglobin to less than 7.0%.

Dyslipidemia: The treatment of dyslipidaemia with statins reduces the risk of cardiovascular event in patients with atherosclerosis. The 2013 American College of Cardiology (American Heart Association (ACC/AHA) guidelines recommend consideration of statin therapy for primary prevention in all patients with a 10-year risk of atherosclerotic vascular disease of >7.4% and no longer recommends to a particular lipid level target [38].

Hypertension: Numerous studies show that arterial hypertension is 2-3 times more common in PAD patients than in the normal population. Current European recommendations for antihypertensive therapy in high-risk patients recommend achieving a target pressure of less than 140/90mmHg in non-diabetics and less than 130/80mmHg in diabetics and chronic renal failure patients. The use of ACE inhibitors in PAD patients reduces vascular death, IM and stroke, regardless of their ABI. In addition, the use of ACE inhibitors is associated with lower mortality after infrainguinal reconstruction operations [48].

Hyperhomocysteinemia: shows an independent factor in the development of PAO

Treatment: coronary heart disease, lung disease, and renal failure

Local risk factors that contribute to the development of skin necrosis must also be intensively treated. Edema, infection (antibiotics by culture, local wound treatment, necrectomy, incision, drainage of abscesses)

Education of patients: The patient must cooperate: requires regular medication, a lifestyle change with a healthy diet is needed, the patient must give up smoking, increase physical activity, change eating habits and reduce excess body weight[49]. In particular, the diabetic foot is a serious medical problem. Training exercises under supervision are part of the treatment.

General measures: bed rest, limb positioning, prevention of pressure sores, treatment of pain, epidural anesthesia, treatment of the swelling.

Epidural and spinal cord stimulation

Lumbar sympathectomy:

Intermittent pneumatic compression

Retrograde intravenous perfusion

Alternative medicine: Mainly in connection with IV. Stage of PAD, several options are confirmed. There are no control studies confirming their validity. Alternative medicine includes hyperbaric oxygen therapy, external application of growth factors, enzyme therapy.

Amputation: this remains the last option to avoid or halt general complications of irreversible limb ischemia. For bedridden patients, femoral amputation may be the best option

Revascularisation - Intervention and Surgical Treatment for Chronic Lower Limb Ischemia

Lower extremity revascularization may be endovascular, open or a combination of both. In high-income countries, there has been an increase in the proportion of patients undergoing endovascular revascularization procedures, with decreasing open-surgical revascularisation procedures, in-hospital mortality and major amputation [50]. Changed new recommendation in PAD guidelines for infra-popliteal lesions is: endovascular first (IIa level), bypass using GSV (I level), and endovascular therapy (IIa level) [40].

The aim of the treatment: in the claudicants is the prolongation of the claudication interval, and in the CLI it is the removal of pain and healing of the defects as well as the salvage of the functional limb.

The choice of appropriate treatment is individual and depends on a number factors, including clinical presentation (Rutherford classification-functional stage of the disease), TASC classification of lesions, and the general condition of the patient [51]. The choice of method depends on the extent of the disease, co-morbidity, technical possibilities, and evidence base of results. In new concept: ESC guidelines (Concept for Lower extremity artery disease) [40]- Chronic limb-threatening ischemia (CLTI) defines the most severe form of PAD in lower extremities. Beyond ischemia, wound and infection should be evaluated to stratify the amputation risk (new Wifi classification) [52]. TASC classification excluded from the guidelines.

Investigations prior to revascularization: risk factors, previous interventions, and cerebrovascular events. It is important to thoroughly evaluate the patient's overall condition and risk. The extent and location of the disease are confirmed by DUS, CTA, MRA, or by angiography. It is also important to examine the venous system [38].

Indications for revascularization of lower extremities are: limiting claudication, rest pain and non-healing arterial defects when we can improve the patient's quality of life and we can expect to survive for several months [51].

Contraindications for revascularization of lower extremities are: in patients with resting ischemic pain, extensive non-healing wounds, and gangrene, overwhelming sepsis arising from the foot, late presentation of acute limb ischemia. Then primary amputation is often the best treatment alternative [45].

Figure 7. Irreversible ischemia of lower extremities.

Figure 8. Failed revascularization and demarcation of ischemic area.

The Transatlantic Consensus (TASC) was established in 2000 under prof. J. Dormandy and R.B Rutherford. It concerns epidemiology, diagnosis, and treatment of PAD [45]. Sixteen European and North American professional companies participated in its processing. After completion in r. 2007 was the TASC II document established [3].

TASC [45] classified PAD based on anatomical localization and disease severity (ABCD). In general, endovascular treatment is recommended for A/B type lesions and surgical treatment for C/D type lesions. Both modalities of intervention for B/C lesions are accepted. The choice depends on the patient's risk and the surgeon's experience [53], estimated duration of intervention, presence of a suitable vascular graft [54] and the patient's preference should also be taken into account. The determinant of success in endovascular therapy is the anatomical and morphological characteristics of the lesion. In open revascularization it is the quality of bypass [3, 24, 51]. For both types of revascularization the quality of "run off" arteries is important. Recent works suggest that direct revascularization of the ischemic site with a direct revascularization procedure to the source artery (angiosome-distinct block of tissue fed by source arteries, the area with tissue loss) has better results than indirect revascularization in interventions [55].

Table 3a. TASC classification of femoropopliteal lesions TASC II 2007 – summary recommendations

Segment/ recommendations	Mostly PTA Type A	PTA preferred Type B	Surgical treatment preferred Type C	Mostly surgical treatment Type D
Femoral	Stenosis AFS below 10 cm or occlusion below 5 cm	Stenosis AFS or occlusion below 15 cm	Stenosis AFS or occlusion more than 15 cm	Complete AFS or popliteal occlusion
Popliteal	Occlusion below 5 cm	Popliteal stenosis	Recurrent disease	
Crural	Here, there are not categories A and B		Stenosis below 4 cm or occlusions below 2 cm	Diffuse disease or oc- clusions above 2 cm
Results	There are excellent results in both groups A and B		PTA/stent has a tempo- rary effect and is indicated if surgery is contraindicated for technical causes, or for the patient	Endovascular approach is not recommended, it is possible only in case of critical ischaemia, and impossibility of surgical treatment

Table 3b. TASC classification of femoropopliteal lesions TASC II 2007 – summary recommendations**2007 Classification of
femoropopliteal lesions**

TASC Type A Femoropopliteal
lesions:
Single stenosis ≤ 10 cm in length.
Single occlusion ≤ 5 cm in length.

TASC Type B Femoropopliteal
lesions:
Multiple lesions, each ≤ 5 cm
(stenoses or occlusions).
Single stenosis or occlusion
 ≤ 15 cm not involving the infra-
geniculate popliteal artery.
Single or multiple lesions in the
absence of continuous tibial
vessels to improve inflow for a
distal bypass.
Heavily calcified occlusions
 ≤ 5 cm in length.
Single popliteal stenosis.

TASC Type C Femoropopliteal
lesions:
Multiple stenoses or occlusions,
totalling >15 cm, with or without
heavy calcification.
Recurrent stenoses or
occlusions that need treatment
after two endovascular
interventions.

TASC Type D Femoropopliteal
lesions:
Chronic total occlusion of the
superficial femoral artery
(>20 cm, involving the popliteal
artery).
Chronic total occlusion of
popliteal artery and proximal
trifurcation vessels.

**2007 TASC II
Consensus**

Endovascular is the
treatment of choice.

Endovascular is the
preferred treatment**.

Surgery is the preferred
treatment for good-risk
patients**.

Surgery is the
treatment of choice.

First and foremost, good patency of the aortoiliac bed must be ensured before infrainguinal vascular reconstruction can be performed [56]. However, complex reconstruction requires adequate operational risk, appropriate graft, and sufficient outflow [57].

In general, if there is a choice between endovascular and surgical treatment, the first option is preferred. The choice depends on the extent and degree of arterial disease. The risks and prospects of success for each case need to be considered.

Endovascular Treatment for PAD

While the frequency of surgical interventions is decreasing, the number of endovascular interventions has increased several times. Thanks to the continuous improvement of techniques and technologies, it is more effective and long-term results demonstrate safety and durability. PTA and stenting are most commonly used for the revascularization of short and medium length lesions, the development of new techniques and technologies such as subintimal angioplasty, stentgrafts, mechanical and laser atherectomy allow for longer stretches of recanalization and many vascular specialists promote endovascular treatment first.

Technically, the methods can be combined. The development of drug-eluting stents (DES) and drug-coated balloons with the antiproliferative drug paclitaxel (DCB) offers the possibility of reducing the number of restenosis after endovascular treatment. The Tack Endovascular System spot treats dissections with a short 6mm long self-expanding stent - reduces the amount of metal, thereby reducing the inflammatory response. Endovascular treatment is less invasive and also suitable for high-risk polymorbid patients with reintervention if needed. For a low incidence of complications, it is recommended as the first choice method. For the patient, it is preferred that after diagnostic angiography (which remains the gold standard in the investigation of PAD) if the planned revascularization is followed immediately by the endovascular intervention [58].

Figure 9. Balloon angioplasty (left iliac artery).

Figure 10. Stent in left superficial femoral artery.

An immediate technical success rate of infrapopliteal interventions is reported in the range of 82-98%, 1-year primary patency 78-85%, and more than 86-97% success in limb salvage. Drug-eluting stents have been proven to be the most durable therapy for short-to moderate-length lesions below the knee [50].

Complications of Endovascular Treatment

About 10% of patients after endovascular interventions have complications that may result in open surgery, amputation or death (hematoma, thrombosis, dissection, pseudoaneurysm, a-v fistula, bleeding, peripheral embolism, infection, foreign body, endoleak, implant dislocation) Overall complications: renal failure, IM, stroke in 1% [59].

However, endovascular interventions have shorter duration than surgical bypass, and more frequent reinterventions are needed, especially in cases of diffuse or long occlusions [24].

Surgical Treatment for PAD

Surgical treatment is an option. Bypass, with a venous conduit of high-quality vena saphena magna (VSM), represents the gold standard for revascularization, especially in CLI [57, 59, 60] and are confirmed by many studies [53]. Despite the promising results of intervention therapy, surgical treatment-bypasses-are still needed in a specific group of CLI patients. Femoropopliteal bypasses have excellent long-term results, even where endovascular treatment was not possible [61]. Surgical treatment is still the gold standard (the basis of chronic ischemic limb management) and is still widely used mainly for the aortoiliac area where long-term patency is high (about 90% in 1 year).

An extensive BASIL study [59,62] found no significant difference in one-year survival with a preserved limb (71% in surgery and 68% in endovascular treatment), patients after surgery who survived more than 2 years after the intervention had significantly lower risk of amputation and death.

Recommendations referring to BASIL trial: revascularization for CLI: survival presumption less than 2-years - recommended as first balloon angioplasty, especially if no autologous vein is available. Presumption of survival for more than 2-years - bypass surgery is usually recommended as first-line treatment, especially if a suitable autologous vein is available.

Neville et al. [63] noted that open surgery compared to endovascular procedures resulted in significantly faster and more frequent complete healing of the wounds.

In CLI, lesions are most commonly localized in the femoral and crural arteries, especially in patients with diabetes mellitus where the lesions are diffuse and multi-stage [64]. Proximal lesions are less common, and infrainguinally there is an assumption of multi-stage changes. In these conditions, femoropopliteal and femorocrural bypasses, possibly popliteocrural, femoro or popliteopedal bypasses are needed for reconstruction. Patients undergoing revascularization for CLI had 88% 1-year limb salvage [24]. Perfect detailed angiography with visualization of pedal vessels is essential for these procedures.

Profundoplasty or iliofemoral interposition has the highest importance as an inflow procedure [50].

Figure 11. Venous femorotibialis posterior bypass placed subcutaneously.

Infrainguinal Reconstructions

Several procedures according to the type of occlusion are available for reconstructive surgery for peripheral arterial vascular occlusions [24, 45].

- Semi-closed femoropopliteal endarterectomy: It cannot be considered a standard operation as it has low patency [65, 66].
- Endarterectomy with or without patch - common femoral artery disease is treated almost exclusively by an open surgery.
- Surgical bypass conduit should preferably be a single graft, but splicing of venous segments is sometimes required. If a tibial anastomosis is performed with synthetic material a vein cuff is generally recommended to improve patency.

- Above-knee femoropopliteal bypass in CLI which can provide at least one in-line blood vessel to the foot
- Below-knee femoropopliteal bypass: Conduit can be placed subcutaneously on the medial side of the knee joint or subfascially in the popliteal area.
- Bypasses to crural vessels - All can be led subcutaneously or along the course of the vessels [18].
- Femoropedal bypass

Figure 12. Bypass femoropoplitealis proximalis.

Figure 13. Bypass femoropoplitealis distalis.

Proximal anastomosis at the site with adequate inflow should be undertaken. It would be the common femoral artery, but maybe SFA or PA, even profunda femoris artery (PFA) [9, 16]. Location of distal anastomosis: a place where run-off is appropriate [67].

Figure 14. Bypass popliteo-tibialis posterior.

Figure 15. Venous femorocrural bypass cum VSM - anastomosis end to side to ATP.

Figure 16. Femorocrural bypass with successful complete revascularisation of crural vessels (angiography).

Profundoplasty - isolated endarterectomy and patch repair of the profound femoral artery. It has value in improving direct perfusion to the thigh and indirect to the calf. It may reduce the severity of claudication and ischemic rest pain in patients in III. and IV. stage of the disease usually leads to the disappearance of resting pain, but the healing of larger trophic defects is inadequate [68].

Another method of limb salvage in critical ischemia with extensive defects is the combined pedal bypass method and free muscle lobe. It is a technically very demanding operation that requires the cooperation of a vascular surgeon and a plastic surgeon who has skills in microsurgery [27]. By combining pedal bypass and free muscle lobe, good results can be achieved in patients with non-healing diabetic ulcers.

In CLIs where arteries are not reconstructable, venous arterialization is still possible. This method may be the last option for limb salvage. The average one-year limb salvage is in the range of 64-77%, and the annual secondary bypass patency is 39-53% [69].

Table 4. Recommendations on revascularisation of femoropopliteal occlusive lesions (for patients with intermittent claudication and severe chronic limb ischemia)

Recommendations	Class ^a	Level ^b
An endovascular-first strategy is recommended in short (i.e. <25 cm) lesions. ^{302,303}	I	C
Primary stent implantation should be considered in short (i.e. <25 cm) lesions. ^{304,305}	IIa	A
Drug-eluting balloons may be considered in short (i.e. <25 cm) lesions. ^{77,306-310}	IIb	A
Drug-eluting stents may be considered for short (i.e. <25 cm) lesions. ^{302,303,311}	IIb	B
Drug-eluting balloons may be considered for the treatment of in-stent restenosis. ^{312,313}	IIb	B
In patients who are not at high risk for surgery, bypass surgery is indicated for long (i.e. ≥25 cm) superficial femoral artery lesions when an autologous vein is available and life expectancy is >2 years. ³¹⁴	I	B
The autologous saphenous vein is the conduit of choice for femoro-popliteal bypass. ^{284,315}	I	A
When above-the-knee bypass is indicated, the use of a prosthetic conduit should be considered in the absence of any autologous saphenous vein. ²⁸⁴	IIa	A
In patients unfit for surgery, endovascular therapy may be considered in long (i.e. >25 cm) femoro-popliteal lesions. ³¹²	IIb	C

^a Class of recommendation.

^b Level of evidence.

^c These recommendations apply for patients with intermittent claudication and severe chronic limb ischaemia.

Combined and Hybrid procedures: Hybrid surgical procedures in vascular surgery represent the use of a combination of endovascular techniques and conventional angiosurgical procedures in one session.

Endovascular and conventional angiosurgical techniques can be combined over a period of time - combined procedures: conventional angiosurgery - endovascular performance, or endovascular performance - conventional angiosurgery. Hybrid and combined operative and endovascular treatments offer less-invasive but effective treatment in patients with multiple artery disease.

Complications after Surgical Revascularizations on the Arterial System

Causes of complications: Errors in surgical treatment as an underestimation of the patient's overall condition, poor evaluation of angiography, underestimation of perioperative findings and technical errors are the most common source of complications [18].

Postoperative complications: are general and typical local for vascular reconstructions:

- Reconstruction closure: a) Early (less than 30 days) - is indicated for revision. The cause may be a poor indication, technical error during the operation, and high peripheral resistance. The solution is a revision, thrombectomy, correction of technical error, graft exchange. Most errors can be avoided using peroperative angiography. b) intermediate: (1-12) months and c) late: (over 12 months). The cause of the last two is thrombosis, fibrosis of the venous valves, intimal hyperplasia, a progression of the disease, scarred scars. The treatment in this case is the correction of left proximal and distal stenoses, in the correction of distal anastomosis, when there was a technical error, further by the new bypass, thrombectomy, thrombolysis, eventually PTA
- Peroperative and postoperative bleeding. The causes are local (cut stitches, ligature slip, suture canal, side structures) and overall (hemostasis disorder and hemocoagulation).
- Pseudoaneurysm in anastomosis: the causes may be on the part of the patient (severe AS changes), material (poor quality) but also the surgeon. Pseudoaneurysms tend to grow with the risk of rupture or thrombosis. The indication for correction is absolute [33].
- Peripheral embolism
- Wound healing disorders in an inguinal area, including lymphatic fistula, cutaneous necrosis of the wound, injury n. saphenous
- Sepsis after peripheral reconstruction in gangrene
- Infection of vascular graft: the most severe threat to the patients' life or vitality of the limb and vascular surgeon confronts a challenging task [70]. The incidence is reported to be between 0.8-6%. Mortality of prosthetic sepsis is 20-75%.
 - Aneurysm during implanted autogenous veins
 - Formation of compartment syndrome
 - Peripheral edema
 - Psychic decompensation: Bohner (2000) in [71] reports a 38.9% incidence of postoperative delirium in patients undergoing reconstructive vascular surgery. Severe postoperative complications are more frequent in these patients (38.1% versus 18.2%).

^a Class of recommendation.

^b Level of evidence.

Aggressive drug treatment reduces cardiovascular mortality while improving bypass patency [24]. In particular, the effects of risk factors should be eliminated [49]. Important are statins and antiplatelet therapies, and anticoagulant therapy [1, 38], if necessary. Single Antiplatelet therapy is recommended in symptomatic PAD (Aspirin 75-100 mg daily, or Clopidogrel 75 mg daily). After a percutaneous intervention, dual antiplatelet therapy (Aspirin and Clopidogrel) is recommended for 1-month, then monotherapy. After open surgery single antiplatelet therapy or oral anticoagulation is recommended [40].

CONCLUSION

Patients with PAD are in high-risk of cerebrovascular and cardiovascular complications. Proper management and assessment of the overall condition with determining the most appropriate treatment are important for disease prognosis. In the healthcare centers, it is recommended to set up a multidisciplinary vascular team to make decisions for the management of patients with PADs [40].

Access to these patients involves early detection of risk factors, elimination of known existing risk factors (smoking cessation, healthy diet, and physical activity) and the proper treatment of diseases such as diabetes and hypertension. Long-term antiplatelet therapy is also essential. In most patients, conservative treatment is sufficient. Interventions are only indicated in case of severe limiting claudication or critical ischemia when a limb is at risk. The first interventional trial in patients with a suitable lesion is endovascular treatment - PTA and additional methods for their low complications and less invasiveness. However, long lesions continue to demonstrate poor patency.

Interventional therapy may be endovascular or classical open surgery or a combination of both. Bypass surgery when using autologous VSM remains the gold standard. Primary amputation has a diminishing role in the treatment of CLI with expansion of endovascular techniques [50].

UPPER EXTREMITY VASCULAR DISORDERS

Upper extremity vascular disorders are less common compared to lower-extremity vascular disease. They affect about 10% of people. Most patients with upper extremity peripheral arterial disease are asymptomatic. Thanks to a good network of collaterals [72] patient's difficulties are considerably smaller. On the other side, the disorders can cause problems such as ischemic pain, blue finger syndrome, open wounds, gangrene, or even loss of body parts.

Causes of Upper Extremity Vascular Disease

The most common causes of upper extremity vascular disease are:

Atherosclerosis: Upper-extremity artery disease due to atherosclerosis is less common compared to lower-extremity artery disease, and the closed sections are usually only short. Mostly is the stenosis or obliteration localized at the level of the brachiocephalic trunk, and the subclavian and axillary arteries and can present as a subclavian steal syndrome (dizziness, syncope, upper arm claudication), or arm ischemia.

Thoracic outlet syndrome: Costoclavicular narrowing can cause functional or fixed stenosis of the subclavian artery in the strait or just behind it and can also involve the vein or brachial plexus. The embolization to the peripheral vessels may occur; most frequent are symptoms due to pressure on the brachial plexus.

Embolic: Arterial limb embolism results in a sudden finger, hand, forearm, and sometimes shoulder pain. Acral parts are pale and cool. According to the degree of ischemia, sometimes we can find partial or complete sensory loss and muscle paralysis (motor or sensory impairment). Embolism is mostly associated with atrial fibrillation or follows a myocardial infarction.

Figure 19. Hand necrosis as a result of late diagnosis of embolism the a. axillaris.

Aneurysms are uncommon but may cause serious problems (ischemia, peripheral embolization). Possible causes can be atherosclerosis, thoracic outlet compression syndrome, congenital abnormality of the origin and the course of the right subclavian artery, repetitive trauma to hands.

Other systemic diseases and anatomic abnormalities that can cause upper extremity vascular disease:

Vasculitis, Giant cell arteritis, Takayasu arteritis, Radiation artery fibrosis, Buerger's disease, Raynaud's disease, Fibromuscular dysplasia, Ergotism, Cytotoxic drugs, Arterial drug injection, Diabetes mellitus, Myeloproliferative disorders, hypercoagulable status, cryoglobulins, repetitive trauma, injury, iatrogenic lesions. Connective tissue disease and several arteritides are infrequent causes of upper-extremity occlusive disease [73].

Figure 20. Upper limb ischemia in systemic disease.

Symptoms of Upper Extremity Vascular Disease

Figure 21. Hand ischemia in steel syndrome.

Figure 22. Hand ischemia in steel syndrome.

Symptoms of upper extremity occlusive vascular disease include discomfort, muscle fatigue or ischemic rest pain, claudications, tightness, heaviness, cramping, or weakness in one or both of arms. Digital necrosis or athero-embolisation is less common. Stenotic lesion of a brachiocephalic and left subclavian artery may present with upper extremity ischemia or vertebrobasilar insufficiency.

Diagnosis

Clinical history: personal and family history, risk factors and comorbidities, lifestyle habits, previous occupations, pertinent medical history, risk factors for atherosclerosis. Establishing whether symptoms are the result of vasospasm or a fixed arterial obstruction [73]. The former is characterized by intermittent symptoms. The manifestations of obstruction are generally unremitting.

Clinical examination: pulse palpation including axillary, brachials, radial, and ulnar pulses, palpation, and auscultation of the supraclavicular region, blood pressure should be measured in both arms (asymmetric). When thoracic outlet syndrome is suspected, the Adson maneuver, in which the head is rotated away from the involved side, is performed, Allen's test [74]

Laboratory testing: When clinically suspected, it can be assessed by

Duplex ultrasound (DUS)

Computed tomography angiography (CTA) or

Magnetic resonance angiography (MRA),

Digital subtraction angiography (DSA),

Positron emission tomography is useful for the diagnosis of arteritis (Takayasu disease, giant cell arteritis) [40].

Treatment for Upper Extremity Vascular Disease

Treatment varies from pharmacological therapy for vasospastic and vasculitis syndromes to endovascular and operative approaches for stenoses and occlusions.

In most asymptomatic patients, medical treatment is the option of choice. However, the goal is also to treat the underlying causes (risk factor control). Trombolytic agents have been used to recanalize medium and small vessel occlusions with variable success [75].

When revascularization is considered, both endovascular and open surgical options can be proposed, according to lesion characteristics and the patient's risk.

Revascularization can be proposed in cases of severe/disabling symptoms, bilateral stenosis, stenosis with ipsilateral arteriovenous fistula for dialysis, patients planned for coronary artery bypass graft surgery or those already operated on with ipsilateral internal mammary artery grafted to coronary arteries with evidence of myocardial ischemia [40]. Open surgical approach and endovascular treatment can both be proposed according to lesion characteristics and the patient's risk including angioplasty and stenting, transpositions (subclavian-carotid), bypasses (carotid-subclavian, axilloaxillary, carotidaxillary, carotidcarotid bypass, and thoracic outlet surgery).

Table 7. Recommendations on the management of subclavian artery stenosis [40]

Recommendations	Class ^a	Level ^b
In symptomatic patients with subclavian artery stenosis/occlusion revascularization should be considered	Ila	C
In symptomatic patients with a stenotic/occluded subclavian artery, both revascularization options (stenting or surgery) should be considered and discussed case by case according to the lesion characteristics and patient's risk	Ila	C
In asymptomatic subclavian artery stenosis, revascularization:		
◆ should be considered in the case of proximal stenosis in patients undergoing CABG using the ipsilateral internal mammary artery	Ila	C
◆ should be considered in the case of proximal stenosis in patients who already have the ipsilateral internal mammary artery grafted to coronary arteries with evidence of myocardial ischaemia	Ila	C
◆ should be considered in the case of subclavian artery stenosis and ipsilateral arteriovenous fistula for dialysis	Ila	C
◆ may be considered in the case of bilateral stenosis, in order to be able to monitor blood pressure accurately	Ilb	C

CABG= coronary artery bypass graft surgery.

^a Class of recommendation.. ^b Level of evidence.

Thoracic Outlet Syndrome

Thoracic outlet syndrome (TOS) describes a variety of symptoms caused by compression of the brachial plexus or subclavian vessels at the thoracic outlet (costoclavicular narrowing). In more than 90% of all thoracic outlet syndrome [76] symptoms are neurological. There is controversy concerning the diagnosis and treatment of N-TOCS (neurogenic thoracic outlet compression syndrome). Arterial complications are often associated with bone abnormalities. The initial arterial lesion is fibrotic thickening with intimal damage and post-stenotic dilatation, leading to aneurysmal degeneration with mural thrombus and the risk of

embolization [73]. Arterial reconstruction and first rib or cervical rib resection are indicated in all patients with arterial complications of TOS.

Upper limb embolism: presents with symptoms that include pulselessness, pallor, pain, and paresthesias. Emboli of cardiac origin are most common, particularly in patients with atrial fibrillation [19] or following myocardial infarction. The brachial bifurcation is the most frequently involved site for an embolus to lodge. Most emboli can be retrieved through a distal brachial transverse arteriotomy [73].

CONCLUSION

Vascular diseases of the upper extremity are rare in comparison to those involving the lower extremities. Upper extremity arterial disease evaluation, diagnosis, and treatment represent a much different spectrum than those of lower extremities. The management is difficult and requires an assessment of vascular structure and function.

Upper extremity vascular disease due to atherosclerosis is mostly situated at the level of the brachiocephalic trunk and the subclavian and axillary arteries.

When clinically suspected, it can be assessed by DUS, CTA, or MRA.

In most asymptomatic patients, medical treatment is the option of choice. Revascularization can be proposed in cases of severe disabling symptoms, bilateral stenosis, stenosis with ipsilateral arteriovenous fistula for dialysis, patients planned for coronary artery bypass graft surgery or those already operated on with ipsilateral internal mammary artery grafted to coronary arteries with evidence of myocardial ischemia.

When revascularization is considered, both endovascular and open surgical options can be proposed, according to lesion characteristics and the patient's risk [40].

Chapter 290

VASCULAR TRAUMA

Ivan Kopolovets*, MD, PhD

Department of Vascular Surgery, East Slovak Institute of Cardiovascular Diseases,
Kosice, Slovakia
Uzhhorod National University, Medical Faculty, Department of Surgical Diseases,
Uzhhorod, Ukraine

ABSTRACT

Clinical manifestations of vascular trauma are diverse. The severity of the patient's condition depends on the nature of the vascular trauma, the extent of blood loss, co-existent soft tissue, vein, nerve, and bone injuries, and ischemia duration. Adequate assessment of the patient's condition allows choosing appropriate treatment tactics and improving treatment results. Reconstructive surgeries provide successful treatment of vascular injuries.

INTRODUCTION

Among different trauma types, great vessel traumas account for 2% of the cases [1]. Clinical manifestations of vascular trauma are diverse and are determined to a large extent by the nature of vascular wall injury, the caliber of the damaged artery, the anatomical and topographic peculiarities of the damaged area, the presence of co-existent vein, bone, or nerve injury, the extent of the affected soft tissues, the severity of the patient's general condition, the extent of blood loss, the degree of ischemia, etc. [2, 3].

There are various classifications of vascular traumas; however, the most commonly used classifications are those involving trauma mechanism and localization, the nature of clinical manifestations, and the effects of vascular trauma [1].

Classification of Vascular Traumas [4]

Open Injury

1. By trauma mechanism:
 - vulnus punctum;
 - vulnus incisum;
 - vulnus caesum;
 - vulnus congruassatum;
 - vulnus sclopetarium.
2. By the nature of vascular damage:
 - tangential wound that does not extend into the lumen;
 - lateral wound;
 - penetrating wound;
 - circular rupture of the vessel with the loss of its portion along its length;
 - circular rupture of the vessel without the loss of its portion along its length.
3. By clinical manifestations:
 - recent traumas:
 - a) external bleeding;
 - b) anemia;
 - c) shock;
 - d) ischemia;
 - e) limb gangrene.
 - traumas complicated by:
 - a) pulsatile hematoma;
 - b) secondary bleeding;
 - c) infected hematoma.
4. By the degree of damage to the surrounding tissues:
 - isolated artery or vein injury:
 - a) single;
 - b) multiple;
 - combined artery and vein injury.

Closed Injury

1. By trauma mechanism:
 - blow;
 - compression;
 - sprain.
2. By the nature of vascular damage:
 - bruise without intramural hematoma;
 - bruise with intramural hematoma;
 - rupture of single layers of the blood vessel;
 - blood vessel rupture:
 - a) intraparietal;
 - b) circular.
 - crush of all the layers of the blood vessel;
 - compression of the vessel by a bone fragment or a sprained limb segment;
 - puncture of the vessel wall with a bone fragment;
 - disconnection of the lateral branch from the vascular trunk.
3. By clinical manifestations:
 - recent traumas
 - a) shock;
 - b) arterial spasm;
 - c) intermuscular hematoma;
 - d) ischemia;
 - e) limb gangrene.
 - traumas complicated by:
 - a) pulsatile hematoma;
 - b) joint contracture in the affected limb;
 - c) venous or arterial insufficiency.
4. By the degree of damage to the surrounding tissues:
 - isolated injury;
 - combined injury to the great vessels and the surrounding tissues or the internal organs;
 - The effect of the injuries to the great vessels:
 - traumatic arterial aneurysm;
 - traumatic arteriovenous fistula;
 - disease of the ligated vessel;
 - ischemic contracture

Recent traumas are those diagnosed within the first 3 days after occurrence. Complicated traumas include those diagnosed since the 3rd day after occurrence within the next 6 weeks [5].

The classification is according to a three-level system, which is based on the wound localization and the possibility to stop bleeding. [6].

Level 1: Peripheral injuries are localized distally from the axillary artery or vein (the upper limb) or the common femoral artery or vein (the lower limb) and are responsible for the

smallest percentage (14%) of bleeding-related fatalities. This was mainly due to wide distribution of the emergency military tourniquets or compression bandages which were used in 56% of the cases.

Level 2: Proximal axillary vessel injuries or axillary vessel injuries. Bleeding is difficult to stop with a compression bandage or a tourniquet.

Level 3: Intracavitary injuries to the chest or the abdomen and pelvis. To treat this category of patients is a very difficult task due to noncompressible truncal hemorrhage (NCTH) which is the main cause of death in approximately 67% of the cases.

This categorization scheme is most useful for penetration or battlefield trauma. However, it can be used for any vascular trauma related to bleeding. Today the AAST-OIS (the American Association for the Surgery of Trauma Organ Injury Scaling) classification for traumatic vascular injuries including the cervical, thoracic, abdominal and peripheral regions is available [7]. This classification system focuses primarily on the precise identification of the blood vessel and does not involve the severity of vascular trauma or the degree of hemorrhage or ischemia. Thus, it provides little additional information on the results or treatment. The clinical picture of vascular injuries includes general and local signs.

Clinical signs depend on the nature of the injury, the damaged vessel size, the presence of bone or nerve injury, the extent of soft tissue injury, the patient's general condition that depends on the severity of blood loss, the presence of shock, and the degree of limb ischemia. In open vascular injuries, the first clinical signs are bleeding and manifestations of anemia in the form of pale skin, low blood pressure, and tachycardia [8, 9].

Local signs of open arterial injury include its localization in the projection of the blood vessels, external arterial bleeding, hematoma, and the phenomena of limb ischemia [10]. In a partial rupture of the artery, bleeding usually lasts longer than in complete rupture of the artery when it can stop due to arterial contraction, an inward twisting of the intima followed by thrombosis of the lumen which is caused by the development of hypotonia. The absence of bleeding does not exclude arterial injury. In arterial injury, a pulsating mass is often formed. Tense pulsatile hematoma is usually limited, being located along the blood vessel. An important sign of arterial damage is a weak or absent pulse within the vessels located distal to the damaged area [11]. In 80% of the cases, the signs of inadequate blood supply to the limb in the form of ischemic pain and impaired sensitivity. Ultrasound scans should be an integral part of the algorithm for examining the patients with injuries to the great vessels [3]. In arterial injuries, the primary goal of treatment is to save the patient's life and then to preserve limb viability and restore normal limb functions. Therefore, the main task is to stop bleeding.

Bleeding can be stopped in the following ways [12, 13]:

- to press down on the artery proximally to or at the site of damage with a finger;
- to apply a sterile pressure dressing;
- to apply tamponade in combination with a compression bandage;
- to apply a tourniquet;
- to ligate the artery;
- to apply the hemostatic forceps.

Tamponade

The effectiveness of tamponade depends on its proper application. The closer a tampon is to the site of vascular injury in the wound is inserted and the tighter it is, the faster the desired effect is achieved, especially in the cases when the injury is on the lateral wall of the vessel.

Hemostatic Forceps

A safer method to clamp off blood vessels is to apply the hemostatic forceps. However, this procedure may be accompanied by damage to the surrounding nerve trunk and crushing of the arterial wall along its length. These factors should limit the use of forceps, which are not intended to stop bleeding. In such cases, atraumatic vascular clamps with a ridge surface are advisable. To clamp off small blood vessels, it is better to use the bulldog clamps.

Tourniquet Application

The tourniquet should be applied as close as possible to the site of vascular damage while protecting the underlying tissues with a soft pad. The tourniquet should be removed or loosened every hour while applying finger compression over the artery to stop bleeding. The tourniquet should be applied as tightly as necessary until the bleeding stops. In venous injuries, if the tourniquet is not tight enough, it increases bleeding. It is recommended to avoid tourniquet application if possible, as it results in critical limb ischemia. In addition, the tourniquet is a strong shock-producing factor which increases the risk of infectious complications.

Temporary Prosthesis

The use of temporary prosthesis allows the stoppage of bleeding, the restoration of regional hemodynamics, and the prevention of irreversible changes in the affected limb; it also creates favorable conditions for limb-sparing surgery.

Artery Ligation

Artery ligation should be performed only if there are strict indications. They include the cases when reconstructive surgery is impossible, since the patient's condition is critical, when secondary erosive bleeding occurs from the blood vessels in the infected wound, when vascular damage is complicated by limb gangrene, and when there is damage to the blood vessels that have no functional importance for circulation. In vascular injury, the blood vessel should be ligated as close as possible to the site of vascular damage to preserve more collaterals, which ensure limb viability.

Medical Care at the Prehospital Stage

Medical care for all the patients with vascular trauma at the prehospital stage consists of [9, 14]:

- performing hemostasis (tamponade, compression bandages, temporary shunting, applying hemostatic forceps, etc.)
- ensuring airway patency;

- anti-shock measures, prevention of air embolisms (in venous injuries); prevention of infection (antibiotics, tetanus toxoid); hospitalization of the patient for providing specialized care.

Diagnostics

Diagnostics depends on the patient's condition, the nature of the injury, and clinical manifestations. Optimal diagnostic methods include computed tomography (CT) angiography (Figure 1), diagnostic angiography (Figure 2), and ultrasound scan of the blood vessels [15, 16].

If there is an injury in the projection of the vascular bundle with the symptoms of active bleeding, surgery is performed without any additional examination methods. The indications for arterial reconstructions depend on limb viability, which is not always determined by the time that elapsed since the injury. The localization and nature of the injury, the possibility of collateral circulation, and the state of hemodynamics and microcirculation are important as well [17, 18].

Figure 2. Angiography: Traumatic lesions of popliteal artery.

Surgical Treatment

Cervical Vessel Injuries

The exposure of the carotid arteries and jugular veins on the neck is performed through the incision along the anterior edge of the sternocleidomastoid muscle. The injury to the first portion of the common carotid artery requires the cervical sternal approach [19, 20]. The nature of vascular damage determines the extent of reconstructive surgery. All devitalized tissues are removed. In case of injuries to the external carotid arteries and their branches and the external jugular veins, no reconstructive surgery is needed, and they may be limited to the ligation of the affected vessels. In linear injuries or partial transection of the common and internal carotid arteries, vascular suture is used. In case of complete transection of the artery after resection of the crushed edges, diastasis can be prevented by mobilizing the ends of the blood vessels and creating the circular anastomosis. Vascular trauma that is accompanied by a significant defect in the vessel wall requires autovenous patch plasty or autovenous prosthetic repair (by means of the great saphenous vein) [21, 22, 23] (Figure 3).

Figure 3. Autovenous prosthetic repair of a. brachialis (using the great saphenous vein).

ABDOMINAL VASCULAR INJURIES

The most common causes of abdominal vascular injuries are penetrating traumas caused by sharp, pointed objects and gunshot traumas, which account for 90% of all abdominal vascular injuries. Blunt abdominal trauma which is accompanied by vascular damage (up to 9%) usually results from motor vehicle collisions. The inferior vena cava is the most commonly injured abdominal vessel (41%); the abdominal aorta is relatively rarely injured in blunt traumas (17%). Isolated abdominal aortic injuries account for 2% of the cases. If the abdominal aorta and its branches are damaged and internal bleeding occurs, injured people often die at the scene of the accident [24, 25].

In vascular trauma, the abdomen is conventionally divided into three anatomical areas [24]:

- Zone 1 includes the midline retroperitoneum extending from the aortic hiatus to the sacral promontory. This zone is subdivided into the supramesocolic and

inframesocolic areas. The supramesocolic area contains the suprarenal aorta and its major branches (the celiac axis, the superior mesenteric artery, and the renal arteries), the supramesocolic inferior vena cava with its major branches, and the superior mesenteric vein. The inframesocolic area contains the infrarenal aorta and the inferior vena cava.

- Zone 2 (left and right) includes the kidneys, the paracolic gutter, and the renal vessels.
- Zone 3 includes the pelvic retroperitoneum and contains the iliac vessels.

Some authors add Zone 4 in the perihepatic area that contains the hepatic artery, the portal vein, the retrohepatic inferior vena cava, and the hepatic veins [26].

Clinical manifestations of abdominal vascular injury include signs of internal bleeding and damage to the abdominal organs. If after vascular trauma retroperitoneal bleeding occurs, a large abdominal hematoma is formed that can reduce the blood loss. It may be difficult to diagnose blunt abdominal trauma with co-existent vascular injuries in a relatively stable patient's condition. During examination, diagnostic ultrasound should be used first to detect retroperitoneal hematoma or free fluid (blood) in the abdominal cavity. In isolated abdominal aortic injury, intimal rupture followed by aortic thrombosis is rare. Such mechanism of vascular injury is typical for elderly patients with significant atherosclerotic changes when the plaque is detached. In such cases, the determinative symptoms include ischemia of the lower extremities and visceral organs. Retroperitoneal hematoma may not be formed. During the ultrasound scan, the degree of abdominal aortic injury may be determined. Intimal rupture may result in aortic dissection extending distally into the iliac arteries. The presence of the wound penetrating to the abdominal cavity, or the retroperitoneal space on the patient's body always serves as an indication for surgery. Midline laparotomy is considered as an optimal approach in abdominal vascular injuries. When restoring the integrity of the aortic wall and branches, sutures are used, whereas in more serious injuries, autovein plasty or prosthetic repair are applied. In patients with gastrointestinal injuries and co-existent abdominal aortic injuries, when the use of synthetic prosthesis is dangerous due to peritonitis, the extra-anatomic bypass is performed.

Isolated injuries to the visceral branches of the abdominal aorta are rare; they are commonly caused by vascular trauma during surgery. During ultrasound scans, blunt renal trauma looks mostly like perirenal hematoma and is accompanied by impaired urine passage on excretory urograms. The most common signs of blunt renal artery trauma that manifests itself as thrombosis are hypertonia, headache, proteinuria, microhematuria, and kidney pain. Angiography allows detecting renal artery occlusion that is confirmed by retrograde blood flow through the renal vein. In unilateral injury to the renal artery, injury to the celiac artery and the mouth of the superior mesenteric artery, thoraco-phreno-lumbotomy should be performed. In bilateral injury, midline or transverse laparotomy is performed. Reconstructive surgery includes suturing and angioplasty using the allograft or autovein. If there are severe injuries and it is impossible to perform reconstructive surgery, nephrectomy is used [27, 28, 29].

The development of endovascular technique allowed using prosthetic grafts in traumas that has some advantages for a patient, namely less blood loss; neither laparotomy nor long-term anaesthesia is needed. These advantages are successfully used when treating arteriovenous fistulae and posttraumatic pseudoaneurysm [30, 31].

SURGICAL TACTICS FOR MAJOR VEIN INJURIES

The frequency and structure of complications arising in large vein injuries is largely determined by the nature, extent, and localization of trauma and time that elapsed since the injury.

Classification of Venous Injuries

- closed injuries;
- open injuries;
- isolated injuries.

Venous injuries with co-existent damage to:

- corresponding artery.
- limb bones;
- soft tissues;
- large nerve;
- multiple damage.

By the nature of damage:

- complete vein rupture;
- partial vein rupture;
- crushed vein, vein defect;
- lateral, penetrating injuries;
- bruise, vein distortion.

By clinical manifestations:

- uncomplicated;
- complicated by:
 - bleeding;
 - blood loss, shock;
 - venous hematoma;
 - phlebothrombosis;
 - venous insufficiency;
 - limb ischemia;
 - traumatic asphyxia;
 - air embolism.

By venous injury localization:

- neck;
- chest;
- abdomen, pelvis;
- upper extremities;
- lower extremities.

Surgical treatment of venous injuries is characterized by a range of specific peculiarities caused by low blood pressure, slow blood flow, thinness of venous wall, and higher tendency to form blood clots [32, 33].

In venous injuries, bleeding of varying intensity is almost inevitable. However, in some cases, venous bleeding that occurred at the time the vein was damaged or immediately after it stops its own. This characteristic feature of venous bleeding should be always considered, as it may lead to diagnostic and tactical errors at the hospital stage of treatment. The main methods to stop bleeding in the hospital are to apply tamponade or hemostatic forceps, to ligate the damaged veins, or to perform temporary prosthetic repair [34].

Wound tamponade as a method of preliminary or permanent hemostasis may be effective in case of its proper application in combination with a compression bandage. In most cases of venous bleeding, correctly applied compression bandage provides good hemostasis. However, in more than half of the cases, venous injuries are accompanied by damage to the corresponding artery. Therefore, the application of tamponades may be ineffective, as it does not exclude the possibility of re-bleeding.

The application of the hemostatic forceps may be accompanied by damage to the surrounding nerve trunk and crushing of the great vessels that further reduces the possibility of reconstructive surgery. Thus, in venous trunk injuries, atraumatic vascular clamps should be used to arrest bleeding. The ligation of the major veins may be carried out to achieve preliminary or permanent hemostasis. The number of indications for vein ligation is currently decreasing. During vein ligation, venous circulation disorders that result in limb amputation and death are rather rare, while chronic venous insufficiency often causes severe disability [35, 36]. The indications to the ligation of the venous trunks that are extremely critical include the patient's condition, large infectious wounds, injuries to the paired or saphenous veins in the preservation of venous blood flow through the deep veins, and the impossibility of replacing the damaged vessel due to the limited possibilities of autovein plasty [9, 37].

Surgery for Vein Injuries

After surgical revision of the great vessels, vascular clamps or stay sutures are applied to the peripheral end of the injured vein and the proximal branches. Thrombi are removed from the peripheral or central portion of the vein by aspiration, stripping, or by means of balloon catheters. The venous bed is flushed with saline sodium chloride and heparin (100:1). The ends of the injuries vein are treated. The anastomosis should be made in the oblique plane rather than perpendicular to the axis of the vessels that prevents anastomotic stricture and reduces the risk of vein stenosis. When restoring blood flow, the vascular clamp is removed from the peripheral end of the vein [38].

The success of reconstructive surgery largely depends on complete thrombus removal. In case of incomplete blood clot removal, thrombi in the lumen of the venous trunk lead to ascending thrombosis of the venous bed after surgery.

If there is a large vein defect or a minimal tension along the axis, or it is impossible to approximate the ends of the blood vessels after their treatment, autovein plasty is indicated. If the patient's condition is extremely critical and there is an infectious wound, autovein plasty is contraindicated.

In groin injuries and during surgery (phlebectomy of varicose veins, herniotomy, Ducuing surgery, or vein catheterization), the proximal portion of the femoral vein is commonly injured [39].

In most cases of femoral artery injury, heavy bleeding below the inguinal ligament is observed. When stopping such bleeding, the vein is often additionally injured during the application of the hemostatic forceps and closure of the surrounding tissues with sutures. As a result, a wall defect in the femoral vein occurs which requires patch plasty [40].

VASCULAR SURGERY IN OSTEO-VASCULAR INJURIES

In patients with osteo-vascular injuries, bone integrity should be restored first, and then, surgery can be performed to repair damaged blood vessels and nerves. In osteo-vascular injuries, blood flow, especially collateral circulation, is significantly disturbed due to compression by bone fragments, hematoma, swollen tissues, and obstruction by thrombi [41, 42]. In fractures and dislocations, the femoral-popliteal segment is uniquely susceptible to injury. This fact should be considered when providing medical care to patients with knee joint fractures.

Surgical tactics are determined by the severity of ischemic disorders. If it is necessary to transport the patient, temporary prosthetic repair of the blood vessels is performed [43]. The choice of method for vascular reconstruction depends on the degree of damage which can be seen during the revision of the damaged area. Prior to reconstructive surgery, all the thrombi are removed from the peripheral vascular bed using a Fogarty catheter. The rupture and crush of the blood vessels serve as indications for autovein or patch plasty. Considering the importance of adequate venous blood flow, the damaged veins should also be repaired. In irreversible limb ischemia, primary amputation is performed [44, 45].

SURGICAL TREATMENT OF NERVE INJURIES

In some cases of osteo-vascular injuries, nerve damage is observed. In open injuries when nerve damage is obvious, surgery is the only method to restore lost function of the limb. Primary nerve suture results in better results than secondary one if the following principle of surgical treatment is followed: nerve repair must be tension free. If primary nerve repair cannot be performed without any tension, neuroplasty is considered. Nerve suture and neuroplasty should be applied to the limb placed in the physiological position [46, 47].

The following three types of nerve suture are mainly used:

- epineural suture;
- bundle suture;
- funicular suture.

SURGICAL TACTICS FOR TRAUMATIC ANEURYSM

Great vessel injuries can result in traumatic aneurysms. Long and narrow wound channel and parietal vascular injury occurring during trauma contribute to the development of aneurysms as well. The incidence rate of traumatic aneurysm is 6-18%. The diverse nature of great vessel injuries determines multiple variations of arterial and arteriovenous aneurysms. It takes a certain period of time (during which a fibrous capsule is formed around the pulsatile hematoma) for traumatic aneurysm to develop. The period of traumatic aneurysm formation can vary from person to person. Some patients develop aneurysms within 4-8 weeks after injury, while in other patients, it is observed within the first 4 weeks after injury. Thus, it may be difficult to differentiate pulsatile hematoma from traumatic aneurysm [48].

The most common traumatic aneurysms are found in the femoral artery; the popliteal, brachial and common carotid arteries are not a common site for traumatic aneurysms.

In most cases, it is not difficult to diagnose traumatic aneurysms. The most characteristic clinical sign is the presence of a pulsatile bulge over which a systolic murmur is heard. In combined arterial and venous injuries, arteriovenous fistula may develop [49].

TRAUMATIC ARTERIOVENOUS FISTULA

Arteriovenous fistula is an abnormal direct connection between an artery and a vein which occurs in cases of the impairment of vessel wall integrity due to trauma, namely ballistic trauma, knife injury, blunt trauma, etc. [50]. Arteriovenous fistulae usually occur in the areas where the artery is found close to the vein, namely in the neck, the thigh, or the axilla. In arteriovenous fistulae, blood flows directly from an artery into a vein due to the pressure difference between the arteries and veins. The volume of blood flowing through the fistula depends on its diameter. In large-diameter fistula, blood circulates within the venous system. Due to this, central hemodynamics undergoes some changes, namely circulating blood volume increases, cardiac output increases, total peripheral resistance reduces, size of the heart increases, and heart failure develops. The compensation of disorders occurs due to an increase in heart rate, cardiac cavity dilatation, and reduction in peripheral resistance. In addition to the aforementioned changes, there are some other changes associated with increased venous pressure in the area of the fistula which result in vein dilatation, venous valve lesions, and trophic changes. Subjective sensations the patients with traumatic arteriovenous fistulae experience are very diverse. They can include both the phenomena associated with impaired arterial circulation (pain, weakness, limb numbness, etc.) and those associated with impaired venous outflow (limb edema, superficial venous dilatation, trophic changes, etc.). General symptoms associated with impaired cardiac activity (fatigue, shortness of breath, palpitation, pain in the heart area, etc.) are often observed. The diagnosis is made based on the anamnestic data, the patient's complaints, and the results of physical

examination and instrumental methods (Doppler sonography, angiography and CT angiography) which allow accurate determination of the localization of the fistula, its size and shape, the nature and extent of damage to the blood vessels, as well as peculiarities of the collateral circulation. Surgical approach is the leading therapeutic option when treating arteriovenous fistulae. The timing of surgery depends on the degree of regional circulation impairment and hemodynamic impairment. The fistulae resulted in heart failure must be treated surgically as soon as possible. During surgery, after the exposure of the blood vessels and aneurysm sac, the volume of surgery is determined depending on the degree of changes in the wall of the blood vessels that form arteriovenous fistula. If there is only a single channel connecting the artery and the vein, the simplest intervention is used. In this case, arteriovenous fistula may be ligated. The case is considered more serious if there is a direct contact between the wall of an artery and the vein, especially in case of long-standing fistulae which are characterized by the development of significant aneurysmal dilatations. In simpler cases, after the mobilization of the artery and the vein, lateral vascular sutures are used. To prevent recurrence, the muscles or fascia are often placed between the artery and the vein. In cases of extended fistulae and the presence of aneurysm, different modified methods of patch reconstruction and reconstruction by means of prosthetic interposition grafts are used [51].

SURGICAL TACTICS FOR IATROGENIC VASCULAR INJURIES

Arterial injury resulting in hematoma or pseudoaneurysm complicates approximately 1-1.8% of diagnostic studies of the aorta and the great vessels. The major veins can be injured during their catheterization as well. After superior and inferior vena cava cannulation, bleeding from the subclavian vein into the pleural cavity, hemomediastinum, subclavian and iliac vein thrombosis, and large paravasal hematoma in the absence of arterial injury may be observed.

In some cases, venous bleeding as a complication of surgery creates much more difficulties for achieving hemostasis than arterial bleeding. If there is bleeding from the injured vessel, the hemostatic forceps should not be applied without visual control. It is necessary to press down on the vessel with a finger and apply a limb bandage. Quality compression may serve as an effective method to stop bleeding in post-puncture iatrogenic femoral, iliac, and jugular vascular injuries. The attempt to stop bleeding through the closure of vessel bleeding area with sutures, which involves a large amount of surrounding tissue, is considered dangerous as it may result in the involvement of other important structures. Surgeons often try to visualize the blood vessels by widening the wound channel. In this case, bleeding complicates the manipulations within the wound. The hemostatic forceps are applied to the site of suspected injury without visual control that results in additional damage to the blood vessels and nerve trunks. Surgical revision of the major artery and vein should always be carried out in the projection of the neurovascular bundle. After bleeding has stopped, the access to the injured vessel should be carefully widened, and the central and peripheral ends of the artery or the vein should be mobilized. In arterial and venous injuries, reconstructive surgery is typically required. Minor vascular injuries can be repaired by transverse closure or plasty, while major vascular injuries are repaired using shunt or reconstructive surgery by means of auto- or heterogenous material [52, 53].

Postoperative Period of the Patients with Vascular Trauma

The peculiarities of the postoperative period of the patients with vascular trauma are determined by the severity of the general condition, the extent of blood loss, the nature of vascular damage and ischemia degree, the type of surgery, time that elapsed since the injury, and other factors. In addition to general principles of treating tissue injuries, there are some peculiarities of managing the patients after vascular reconstructive surgeries. After surgery, the patients are transferred to the intensive care unit to provide intensive care, control vital body functions, and continue anti-shock therapy [54].

The prevention of wound infection from the very beginning of treatment is of extreme importance. Therefore, the process of surgical wound debridement is strictly regulated. If the area of tissue injury is large, surgical debridement should be carried out as follows. First, contaminated and crushed tissues are excised, and, then, after vascular repair, devitalized tissue is repeatedly removed. Antibiotic therapy with broad-spectrum antibiotics and their combinations should start intraoperatively and be continued for 5-7 days after surgery [34].

The prevention of repaired vessel thrombosis in the patients with vascular injuries in the postoperative period is of great importance as well. For this purpose, indirect coagulants are used. In the postoperative period, anticoagulant therapy should be continued until complete mobilization. In arterial reconstruction, from the very beginning of treatment, antiplatelet agents should be used in addition to anticoagulant therapy [11].

TREATMENT OF POSTISCHEMIC SYNDROME

One of the most serious complications of acute limb ischemia is the body's response to the revascularization of the ischemic limb. The development of homeostatic disorders in response to ischemic limb revascularization is associated with toxic substances developing in tissues in case of circulatory hypoxia that are released from an ischemic organ and enter the bloodstream. In the postoperative period, in order to eliminate intoxication and hemodynamic disorders after blood flow reconstruction, intensive care should be provided for patients with acute limb ischemia. The prevention of limb edema is of great importance. If there are any signs of compartment syndrome, fasciotomy is required (Figure 4) [12, 55].

Figure 4. Fasciotomy in patient with compartment syndrome.

GUNSHOT INJURIES AND EXTREMITY VASCULAR INJURIES

During World War II, bleeding was the leading cause of death on the battlefield (35%), apart from death due to shock and blood loss. At the stage of medical evacuation, extremity vascular injuries accounted for 96% of all vascular traumas. Isolated artery injury was detected in 47.1% of the cases, combined artery and vein injuries were observed in 49.2% of the cases, and isolated vein injury was seen in 3.7% of the cases. The incidence of injuries to the large arteries was as follows: head and neck injuries were diagnosed in 1.21% of the cases; chest injuries were found in 0.54% of the cases; abdominal and pelvic injuries were seen in 1.13% of the cases; upper extremity injuries were detected in 38.5% of the cases; lower extremity injuries were diagnosed in 56.47% of the cases [56].

If acute blood loss is not massive, the body starts to compensate for blood loss. The main compensatory mechanisms are:

- contraction of the small arteries and veins and mobilization of blood from blood pools, which, in combination with tachycardia and accelerated blood flow, helps replenish the blood supply;
- release of the fluid from tissues to the bloodstream;
- reduction in circulatory hypoxia due to the increase in pulmonary ventilation and oxygen uptake by hemoglobin in the lungs in case of rapid breathing.

However, acute blood loss is a factor which significantly contributes to a complicated clinical course of injury due to severe microcirculatory disorders, tissue hypoxia, and decreased immunobiological mechanisms of body's defense. In addition, posthemorrhagic anemia contributes to the development of complications such as pyogenic and anaerobic infections.

Classification of Wartime Extremity Vascular Injuries (Todd E. Rasmussen/Charles J. Fox) BO 160-1

Triage Categories and Management Guidelines for Wartime Extremity Vascular Injuries

Category I: isolated vascular injury

- One surgical team required;
- Vascular injury, restoration of flow, reconstruction, and limb salvage take priority;
- Extremity tourniquet may be removed in the operating room in coordination with the anesthesia team;
- Venous injury should be repaired;
- Complex or lengthy reconstructions acceptable.

Category II: vascular injury in conjunction with other non-life-threatening injuries

- Two-team approach preferable to treat vascular and other injury;

- Vascular injury, restoration of flow, reconstruction, and limb salvage take priority;
- Extremity tourniquet may be removed in the operating room in coordination with the anesthesia team;
- Venous injury should be repaired;
- Complex or lengthy reconstructions acceptable.

Category III: multiple vascular injuries

- Two-team approach preferable to treat multiple vascular injuries;
- Vascular injury, restoration of flow, reconstruction, and limb salvage take priority;
- Extremity tourniquet may be removed in the operating room in coordination with the anesthesia team;
- Diminished role for venous injury repair;
- Diminished role for complex or lengthy reconstructions.

Category IV: vascular injury in conjunction with life-threatening injuries

- Two-team approach optional after life-threatening injury is stabilized;
- Life-threatening torso, neck, or head injury takes priority;
- Extremity tourniquets should remain in place until the life-threatening injury is stabilized;
- Diminished role for venous injury repair;
- Diminished role for complex or lengthy reconstructions.

Clinical Picture of Vascular Injuries

Bleeding is the main sign of vascular injury, being a pathognomonic sign of this injury type. The nature of bleeding allows making diagnosis and determining the extent of emergency care. Bleeding that occurs in gunshot injuries are classified according to time of its occurrence, the nature and caliber of the vessel, and the site of bleeding [45].

Types of bleeding include arterial bleeding, venous bleeding, arteriovenous (mixed) bleeding, capillary bleeding, and parenchymatous bleeding [36].

Depending on bleeding direction, there are external bleeding, interstitial bleeding, and intracavitary bleeding.

Depending on bleeding time, there are primary bleeding, secondary bleeding, initial bleeding, delayed bleeding, and recurrent bleeding or rebleeding.

Diagnostics of vascular injuries are based on the general signs of blood loss and local symptoms of vascular damage:

- history of heavy bleeding after injury;
- general signs of significant blood loss including thirst, heart palpitation, seeing black spots, or floaters, pale skin and mucous membranes, rapid, weak pulse rate, shortness of breath, and sometimes loss of consciousness;
- location of wound channel in the large vessel area;
- skin discoloration and cold limb;

- hematoma that extends along the large vessels;
- absent or weak peripheral pulse distal to the wound on the injured side;
- pulsation and pathologic vascular murmurs during auscultation of the large vessels;
- ischemic pain in the injured limb;
- ischemic contracture.

Principles of Providing Medical Care and Treatment of Patients with Great Vessel Injuries at the Stages of Medical Evacuation

Treatment of gunshot vascular injuries is a difficult task at all the stages of medical evacuation. Serious complications such as bleeding, embolism, ischemic gangrene, acute anemia, paralysis, etc. developing on the battlefield necessitate the proper organization of emergency care.

Treatment of vascular injuries includes the following steps [32, 34]:

- temporary (preliminary) stoppage of bleeding followed by immediate transport of the patient to the surgical department;
- surgery for vascular injury (permanent hemostasis);
- treatment of acute blood loss and prevention of its consequences;
- prevention of ischemic limb gangrene, wound infection and other postoperative complications;
- functional treatment of concomitant soft tissue, bone and nerve injuries.

The main methods of achieving permanent hemostasis in great vessel injury are:

- restoration of vessel integrity (vascular suture, prosthetic repair);
- ligation of the blood vessel in the wound;
- ligation of the blood vessel along its length.

Specifics of gunshot injuries:

1. Each gunshot injury is primary infected.
2. The artery can be closed with sutures in recent injuries by following aseptic techniques; the possibility of postoperative period should be considered.
3. In traumatic aneurysms, surgery should be performed 1.5-2 months after injury.

The need for blood flow restoration is determined by the degree of tissue ischemia:

- compensated ischemia – active movements and sensation distal to injury site are preserved; no vascular surgery is needed;
- uncompensated ischemia – no active movements; dramatically reduced tactile and pain sensations in the limb; blood flow is needed to be restored within the first hours after injury;
- irreversible ischemia – local or total muscle contracture; vascular surgery is not indicated.

SECONDARY BLEEDING

In vascular injuries, in addition to primary bleeding which was stopped by a health care professional or stopped its own, delayed bleeding may occur. Such bleeding is always dangerous as, firstly, it always occurs unexpectedly and is usually massive, and, secondly, it occurs in an anemic, weakened patient [54].

Early secondary bleeding may occur due to pulling the blood clot out from the injured vessel after the patient recovered from traumatic shock and normal blood pressure was restored. Imperfect immobilization and inappropriate transportation play a significant role in the development of secondary bleeding as they contribute to traumatization, displacement of bone fragments and foreign bodies, and obstruction of the injured vessel. Such bleeding occurs within the 1st-5th days after injury [37].

Late secondary bleeding occurs due to infection of the wound, which may result in thrombus melting or necrosis (arrosion) of the vessel walls. In addition, secondary bleeding can be caused by the pressure sores of the injured vessel wall due to the pressure exerted by adjacent metal or bone fragments and other foreign bodies. Sometimes pressure sores may be caused by drainage tubes or tampons which were close to the blood vessel for a long period of time [38].

Secondary bleeding due to the rupture of pulsatile hematoma or traumatic aneurysm is considered a complication. The clinical picture of secondary bleeding includes its unexpectedness.

Warning signs of bleeding include:

- sudden increase in body temperature without any signs of wound infection;
- pulsation at the sites where only murmurs were heard;
- murmurs and pulse disorders;
- presence of blood spots or small blood clots in the wound.

To stop secondary bleeding, the ligation of the blood vessel in the wound is used; however, it is not always possible. In most cases, the blood vessels are ligated along their length. In some cases of secondary bleeding, it is necessary to amputate the limb, since it is the only way to save the patient's life.

The results of treatment can be improved by:

- rapid evacuation of the wounded from the battlefield;
- improved resuscitation methods (blood transfusion before hospitalization);
- reconstructive vascular surgeries.

CONCLUSION

Clinical manifestations of vascular trauma are diverse. The severity of the patient's condition depends on the nature of vascular trauma, the extent of blood loss, co-existent soft tissue, vein, nerve, and bone injuries, ischemia duration. Adequate assessment of the patient's

condition allows choosing an appropriate treatment tactics and improving treatment results. Reconstructive surgeries provide successful treatment of vascular injuries.

Chapter 291

VASCULAR ACCESS FOR HEMODIALYSIS, VENOUS INSUFFICIENCY, AND ITS TREATMENT

Norbert Torma*, MD, PhD

Angiosurgical Department of Medical Faculty of Safarik University,
Košice, Slovakia

ABSTRACT

Chronic kidney disease is characterized by a gradual loss of kidney function. The most common causes of kidney malfunction are diabetes mellitus, high blood pressure, and glomerulonephritis. Chronic renal disease may not be apparent until a kidney function is significantly decreased. Treatment is focused on the treatment of underlying causes to slow the progression of kidney dysfunction. Once kidney functions are significantly impaired and progress to end-stage kidney failure, the patient may need dialysis. There are different types of dialysis, between them hemodialysis with three primary methods to gain access to the blood for hemodialysis. This chapter deals with the creation, maturation of native access, and graft possibilities.

Chronic venous insufficiency is a medical condition in which blood pools in the veins, straining the walls of the vein. Venous insufficiency syndromes are most frequently caused by valvular incompetence in the superficial venous system- the most widely great saphenous vein, but may also be caused by valvular incompetence in the high-pressure deep venous system or may result from the congenital absence of venous valves. Chronic venous insufficiency represents a spectrum of conditions ranging from simple telangiectases or reticular veins to more advanced stages. The most devastating is such as skin fibrosis, bleeding, and venous ulceration. The initial management of insufficiency involves conservative measures to reduce symptoms and prevent the development of secondary complications and the progression of the disease. They include compressive leg garments and pharmacologic therapy. Traditional surgical techniques and newer interventional methods are reserved for an unsatisfactory response to conservative measures and patients with progression of a disease.

INTRODUCTION

Three primary methods are used to obtain access to the blood for hemodialysis: an arteriovenous fistula and a synthetic graft either arteriovenous graft or venous catheter. The type of access is influenced by some factors such as the course of a patient's renal failure and the condition of the vasculature of the upper extremity. Patients can have multiple access procedures, usually because an AV fistula or graft is maturing, and a catheter is still being used.

Chronic Venous Insufficiency typically begins with mild symptoms but left untreated it can progress permanent skin changes with darkened discoloration and more serious medical condition involving bleeding, complicated wounds, and skin infections. Early intervention and prevention of complications as wounds, bleeding, or infections are the goals of treatment. The treatment plan is aimed at decreasing the blood pressure in the veins to reduce swelling and symptoms and increasing the return blood flow back to the heart. The goal of surgical and endovenous procedures in the treatment of chronic venous disease is to remove or obliterate incompetent veins or to isolate the reflux source from the rest of the vascular system.

VASCULAR ACCESS FOR HEMODIALYSIS

Arteriovenous Fistula

Two types of arteriovenous fistula are available- native arteriovenous fistula (AVF) and arteriovenous fistula with a graft (AVG). AVF is the first option for hemodialysis with best primary patency rate and the lowest complication frequency and with lowest mortality and morbidity [1]. AVF is preferred over AVG and central venous catheters. Only in patients with nonoptimal vessel status is AVG preferred over AVF.

The main principles for creating AVF are:

- Handedness- first AVF on a nondominant limb (left in a right-handed person)
- Starting with most distal localization
- The end-to-side technique of anastomosis
- Direct AVF are preferable over transposition

In a forearm, AVF should be localized on the volar surface, an upper arm on the lateral or anterior surface.

AVF must be able to be repeatedly cannulated, part of a vein minimally 10cm long for repetitive cannulations, localized just below a skin, with sufficient blood flow for sufficient hemodialysis.

Creation of AVF minimally six weeks before the first cannulation- time for maturation. AVG ideally two weeks prior cannulation.

AVF maturation is vascular remodeling as a result of increased blood flow in a feeding artery and draining vein [2]. After the creation of AVF blood flow must increase to a level that provides adequate delivery for dialysis machine and vessel must dilate for safe and effective cannulation. Increased blood flow, decreased peripheral resistance, shear, and hoop stress are important factors for dilatation of a vein and thickening of their wall. The thicker wall is important factors allowing repeated cannulation of a vein. AVF is ready for hemodialysis if fulfills rule 6 which say that six weeks after creation, the vein has diameter 6mm, blood flow through AVF is over 600ml/min and vein is no more than 0,6cm below a skin.

Before the creation of AVF is important vascular mapping to prevent problems with AVF maturation. After vascular mapping, with suitable conditions, we can create one of the following AVF: simple direct, transposition, translocation, or percutaneously [3, 4, 5, 6, 7].

Simple direct AVF is made of artery and vein in their normal positions. The vein is transected and then end-to-side (E-S) anastomosed with adjacent feeding artery.

Radio-Cephalic AVF in Fossa Tabatiere (Foveola Radial)

Fossa tabatiere – space between tendon musculus extensor pollicis brevis and musculus abductor pollicis longus on the medial side and laterally tendon of musculus extensor pollicis longus. In this space is localized, up to the fascia vena cephalica and under the fascia branch of arteria radialis. Vena cephalica is anastomosed with a dorsal branch of arteria radialis to create AVF. In local anesthesia (LA), after preparation of artery and vein is performed 5mm long anastomosis E-S [8].

Distal Radio-Cephalic AVF (on the Wrist)

Anastomosis between a.radialis and v.cephalica. The incision in LA is oblique with distant end over a vein. This is typical Cimino- Brescia AVF, but originally with side-to-side anastomosis.

Distal Basilico-Ulnar AVF (on the Wrist)

Distal basilicoulnar shunt between a.ulnaris, and v.basilica. A diameter of artery and vein should be sufficient for the creation of AVF and Allen test must be negative. Under suitable vascular conditions can be created as a second shunt after failed radiocephalic shunt.

Proximal Radio-Cephalic AVF (Forearm)

Similar shunt like distal radiocephalic AVF between a. radialis, and v. cephalica. The incision is again oblique, but anastomosis is localized deeper.

Arteriovenous AV Shunt in Fossa Cubitalis

After exhaustion of all forearm, approaches can be AVF created in the cubital region. This area is sometimes the first option in patients with DM or with obesity, in patients with a hypoplastic vascular bed in the forearm and in patients with postthrombotic changes of a vein in the forearm. AVF in the forearm, mainly in patients with DM and mediocalcinosis, have a higher rate of failure. AVF localized in the cubital region, have in comparison with forearm localization higher rate of steal syndrome. In the cubital region can be as a venous conduit used v. cephalica, v. basilica, v. mediana cubiti or v. perforans (Gracz operation). In this, the last type of AVF, there is the lowest rate of steal syndrome, and through v. mediana cubiti are dilatated both of veins- v. cephalica and v. basilica. Feeding artery in this cubital region is a. brachialis.

Brachiobasilic AVF with Transposition of a Vein

This type of AVF is one of the latest access possibilities in the upper extremity. The reason for transposition is a fact, that basilic vein lays in the subfascial area and for successful puncture and sufficient cannulation should be transposed. Preparation of a vein can be done through one long incision or more shorter ones. After hydrodilatation of a vein anastomosis E-S, long 5mm is sufficient. The procedure can be performed as a one stage operation or two steps of operation (first anastomosis, second transposition). In obese patients is sometimes a better option transposition of a vein over simple anastomosis. Different types of vein transposition shunts are possible, like a simple direct AVF. The proximal part of a vein is left intact, and in the distal portion, tributaries are dissected, and the vein is transposed into a tunnel or pocket that serves as a bed for vein. This procedure can also be performed at a lower extremity and can be performed as a two-stage operation [9, 10].

AV translocation fistula is a technique where a vein is removed from its normal position. The procedure is similar to AV graft techniques. The translocated vein is anastomosed with the feeding artery and outflow vein. This requires venovenous and venoarterial anastomosis. The most frequently used veins for translocation are great and short saphenous veins and femoral vein. The femoral vein is used very rarely because of potentially perioperative severe complications.

AVF in Lower Extremity

In cases when from different reason, it is impossible to perform AVshunt in the upper extremity, it is possible to perform it on the lower extremity. The rate of complication is higher, and cannulation is also more problematic and less comfortable for the patient and personal. The great saphenous vein can be anastomosed with a. tibialis posterior, behind the inner ankle, or with a. popliteal. Another possibility is to perform the loop technique with great saphenous vein and with anastomosis to a. femoralis communis.

AV Graft Techniques

AV graft (AVG) is the second option in patients where it is impossible to perform native AVF. The benefit of this type of access is a shorter time of maturation (healing) in comparison to a native AVF, better cannulation, and longer area of cannulation.

Failure of the Mature Hemodialysis AVF

Primary AVF is defined as an AVF that never been used for hemodialysis or failure of AVF within period three months of use. The risk factor of primary failure is obesity, older age, female gender, cardiovascular disease, thrombophilia, diabetes, and surgeon skills. The incidence of primary failure increases because of the older age of the patient, more frequent comorbidities- as diabetes, PAO, heart disease, and range till 60%. Also, type and its localization influence maturation and patency of AVF [11, 12].

Before creating of AVF is important vascular mapping. Patients with insuitable vessels are not a good candidate for AVF. In these patients, with sufficient and appropriate feeding artery may be the best option AVG [11]. AVG will be a place for hemodialysis and stepwisely higher circulation will dilate veins for secondary access. When planning the first option is nondominant hand. Planning of AV fistula creation is ideally four months before the first cannulation and minimally six weeks before first use. After the creation of AVF, there is an increase in blood flow in the feeding artery, outflow veins, decreasing venous resistance, and starts vascular remodeling called maturation. Due to increased blood flow, increase shear and hoop stress, production and secretion of mediators by endothelium. All these changes lead to dilatation of a vein and thickening of its wall, thanks to the hemodynamic principle, that a perturbed system attempts to return to its baseline stress state. The clinical definition of maturity requires that AVF is used, can be repetitively cannulated and provides adequate blood flow for hemodialysis. The rule of 6 sets by Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines describes parameters associated with the maturity of AVF. The AVF will be usable for hemodialysis if six weeks after creation is the external diameter of vein 6mm, blood flow 600ml/min, and AVF is no more deep as 0,6 cm from the skin. The diameter of matured AVF is important not only for repetitive cannulation but also for providing adequate blood flow. Thickening of a wall decrease hoop stress and decrease the risk of extravasation after cannulation [13, 14].

Process of AVF development goes through three stages:

- 1) Creation of AVF
- 2) Physiologically mature AVF- AVF that has the potential to be a vascular access
- 3) Clinically functional AVF

The most common lesion associated with non-maturation of AVF is juxta-anastomotic stenosis. This stenosis occurs within 4cm from anastomosis, that decreases blood flow, interrupts maturation and can be a cause of early thrombosis of AVF. If blood flow after the creation of AVF is insufficient for maturation, or during maturation significantly decrease, it should be treated by the endovascular intervention (PTA) or by surgical reconstruction. Surgical reconstruction includes the creation of new anastomosis or correction of primary anastomosis, implantation of vein interpositum, vein patching or graft interposition early before thrombus formation.

Arterials stenoses are much less common cause of nomaturation AVF and AVF failure as venous stenosis. Feeding artery is responsible only for 5% stenosis lesion responsible for nomaturation of AVF. A peripheral draining vein in 10% and almost 80% is a stenotic problem directly in AVF (juxta-anastomotic, body of AVF).

Monitoring and Surveillance of AV Access

Not all stenotic lesion needs to be treated. A stenotic lesion is significant if narrowing of a vascular lumen is equal or more as 50% together with clinical symptoms, abnormal finding, and abnormal blood flow. NKF-KDOQI 2004 and Society for Vascular Surgery 2008 guidelines recommend a routine physical examination of AV access every week [14, 15].

Clinical monitoring includes an examination of the AV access, monitoring of problems with hemodialysis, and decrease of Kt/V [16]. Abnormalities during the physical examination as a swelling, pulse, thrill, bruit alterations, problems with hemodialysis or decreased Kt/V may signal problems with AV access. Kt/V is a method for measuring a hemodialysis dose. Kt/V is defined as the dialyzer clearance of urea (**K**) multiplied by the duration of the dialysis treatment (**t**, minutes) divided by the volume of distribution of urea in the body (**V**, ml). An unexplained decrease of Kt/V (> 0.2) during normally prescribe hemodialysis signalize some problem with AV access. Problems with and during hemodialysis such as prolonged bleeding from puncture sites, problems with cannulation, insufficient blood flow in consideration of target blood flow may also signal a problem with AV access. Surveillance includes blood flow intra – access monitoring, ultrasound (US) examination, and measurement of static hemodialysis venous pressure.

For measurement of intra access flow exists several methods. Ultrasound dilution is the most commonly used. Special flow/dilution probes can measure flow by injection of saline solution through the venous line when dialysis lines are reversed. Dilution information as a result of mixing of blood with the saline is collected by the sensor at the arterial line. The flow procedure should be repeated at least three times, and any fluctuation in the flow rate is an indicator of a potential access problem.

Online measurement of dialysate is measured by placing the conductivity probes on the dialyzer inlet and outlet lines from the access and provides a measure of ion flux during dialysis. By changing the dialysate/water proportion, a significant electrolyte gradient is established between the blood and the dialysate, which results in a conductivity change from

the inlet to the outlet port. This is a function of sodium dialysance and reflects the movement of electrolytes into the patient. Access blood flow (Q_A) from dialysate can be calculated with bloodlines in either their normal position (D) or reverse position (D_{rev}).

In variable flow, Doppler measurement is the flow rate calculated from the change in Doppler signal in the access using variable pump rates. This method uses two needles introduced into the access for collecting the blood from the arterial side (Q_A), to feed into the dialysis pump circuit (Q_B), and back to the venous stream from the other needle. The dialysis blood pump circuits form a parallel circuit with access. The Doppler signal is measured in the access between the two needles (Q_R) as a function of the pump rate, which is calculated as $Q_R = Q_A - Q_B$. Using various values of pump speed, a function $S = F(Q_B)$ is modeled and the intercept at which $Q_R = 0$ is calculated.

Glucose pump test uses a constant glucose bolus into the arterial line and withdrawal of blood from the venous line before and after the infusion. By knowing the concentration of the infused glucose concentration (C_i), and measurement of glucose levels before (C_{a1}) and during infusion (C_{a2}) by using bedside glucometer, the access blood flow (Q_a) can be calculated.

Transcutaneous access flow monitor uses an optical sensor that is placed on the skin immediately above the access. An indicator fluid is injected into the venous line that mixes with blood, and effectively reduces changing the hematocrit concentration, recorded over time by the hematocrit sensor. The difference in hematocrit concentration is used to calculate the intra-access blood flow. The method measures the hematocrit concentration in the blood by the properties of reflection of light by red cells.

The thermodilution technique uses the change in dialysate temperature when mixed with blood to calculate the intra-access blood flow rate. With temperature-sensitive thermistors, which detect changes in temperature downstream over a period of time when cold injectate of known volume and heat is introduced in the access.

US measurement of peak velocity flow ratio across a stenotic lesion. A rate > 2 is suspect from severe stenosis.

During static venous dialysis, the pressure is intra-graft pressure measured by dialysis needles connected to a manometer before starting hemodialysis. Ratio $> 0,6$ is suspect from severe stenosis.

Angiography should be reserved for patients with any physical findings of abnormality or by evidence of abnormality by other methods. Noninvasive monitoring methods have high predictive value in detecting hemodynamically significant stenosis. Indications for angiography:

- 1) The suggestion of stenotic lesion by physical examination – pain and arm swelling, prolonged bleeding time from cannulation points, recurring thrombotisation of blood, problematic cannulation of a shunt, highlighted venous collaterals
- 2) Unexplained, persistent, decreased $Kt/V > 0.2$
- 3) Directly measured low flow rate $> 400\text{ml/min}$
- 4) Increasing of a venous pressure $> 150\text{mmHg}$ during three subsequent hemodialyses at flow $200\text{--}250\text{ml/min}$.
- 5) Recirculation of a Urea $> 10\%$

For endovascular therapy are indicated stenotic lesion $> 50\%$ in combination with clinical findings of AV shunt abnormalities, abnormal physical findings, and abnormal blood flow measurement. Endovascular treatment of stenotic lesion by angioplasty become a method of choice for AV access stenosis. The techniques of angioplasty are similar to other angioplasty procedure, with different types of balloons and procedure can be completed with implantation of a stent or stentgraft. Anatomic criteria of successful angioplasty by NKF-K/DOQ is no more than 30% residual stenosis remaining following angioplasty. Patency of angioplasty varies, depending on lots of factors as a type of AV shunt (graft, fistula) or maturity of the shunt (maturated, nomaturated). The expected six months patency of AV access following angioplasty for access dysfunction should be $> 50\%$. If the AV shunt doesn't meet this goal, options include surgical revision or implantation of stents/stentgrafts. Implantation of stents/stentgrafts is accepted in cases where its use extend AV shunt life and salvage of failed shunt. Definite indications for stent/stent graft implantation are:

- 1) Acute angioplasty failure- residual stenosis after angioplasty $> 30\%$, before placement of stent/stentgraft is recommended repeat angioplasty with more extent balloon
- 2) Rapid recurrence- two clinically significant recurrences in a period of three months. If a patient is a good candidate for surgical intervention, should be considered for surgical revision.
- 3) Vein rupture- when the damage of a vein is profuse with extravasation, it must be treated with implantation of stentgraft. In stage III is indicated prolonged balloon tamponade, if problems continue should consider implantation of a stent, if prolonged inflation of a balloon doesn't tend to stabilize the situation. In the stage, IV is indicated placement of a stentgraft over disruption (Table 1).

Table 1. Classification system of vein damage during angioplasty based upon clinical significance

Stage	Clinical significance
I	The blush of radiocontrast adjacent to the vein
II	Extravasation stable- not affecting blood flow
III	Extravasation stable-affecting blood flow
IV	Disruption of vein- unstable extravasation

Complications of an AV Shunts

Bleeding after the operation, creation of AVF can be the result of heparin therapy, due to dysfunction of thrombocytes or imbalance of hemostasis [17, 18].

Surgical bleeding is managed by suture or ligation or repair. Nonsurgical minor bleeding is treated by hemostatic product.

Other cause of bleeding can be venous hypertension due to stenotic venous lesions. Prolonged bleeding from cannulation point is a result of venous hypertension, stenosis in a venous segment or hyperfunction of AVF (long anastomosis). Bleeding combined with compartment syndrome is an indication for urgent surgical therapy [19].

Stenosis of AVF is the most frequent complication and can lead to nonmaturation of an AVF. Primary failure of a shunt is defined as a shunt that has never been used for hemodialysis, or that fails within three months of use [20, 21, 22].

Stenotic vascular lesions can develop anywhere. In matured AVF, the most common type of stenosis is juxta anastomotic stenosis occurring within first 5 cm of AVF, adjacent to the arterial anastomosis. Stenosis can be directly in anastomosis- anastomotic stenosis, in venous juxta-anastomotic stenosis, or combination of both. Sometimes, mainly in transposed AVF, in the juxta-anastomotic area can be swing point stenosis too [23, 24].

Otherwise is swing point stenosis localized more distally from anastomosis in the angle of transposition or cephalic arch. For this type of stenosis is the typical extreme angle of vein involved in AVF or its drainage vein. Cephalic arch stenosis is most frequently in patients with brachiocephalic AVF. Cephalic arch drains blood from a cephalic vein, and arch stenosis can be seen with either type of shunt with cephalic anastomosis.

Central vein stenosis can occur anywhere within a central vein. A patient who had previously implanted central venous catheters, cardiac devices, or other endoluminal devices. Another possibility is compression of a subclavian vein due to costoclavicular compression. Compression veins in patients with thoracic outlet syndrome. Thoracic central venous obstruction encompasses a spectrum of central venous disease and is classified in Table 2. Predominant mechanisms are vein injury by endoluminal device, endoluminal obstruction related to a thrombus, extrinsic compression, and hemodynamic abnormalities causing intimal hyperplasia.

Table 2. Types of thoracic central venous obstruction

Type	Obliterated veins
I	One internal jugular vein, or subclavian vein
II	Brachiocephalic vein unilateral or Ipsilateral obstruction of the internal jugular vein and subclavian vein
III	Both brachiocephalic veins
IV	Superior vena cava with any constellation of others veins

Arterial stenosis is less frequently cause of AVF failure compared with venous stenosis. They can develop at any part of the arterial segment, but stenosis of the anastomosis is a most frequent in association with juxta-anastomotic stenosis. Higher rate of inflow stenosis is in forearm compared with upper arm AVF. Arterial stenosis leads to decreased blood flow and inadequate dialysis and finally to thrombosis of access.

Thrombosis

Almost all thrombosed AVF have associated pathological anatomy. The rate of thrombosis of AVF is one-sixth of the AV graft. Arterial lesions result in a decrease in blood inflow, and venous lesions increase resistance to blood flow, and both can lead to thrombosis. Sometimes stenosis can so diminish blood flow, that it is not detectable. Amount of thrombus varies considerably, in aneurysmal AVF contains a large volume of thrombus. A large volume of thrombus is typical for thrombosed AVF associated with central venous stenosis, or obliteration. In 20% of patients with thrombosed AVF is etiology different from stenosis. Thrombosis of AVF in these cases is due to hypotension, heart failure, dehydration, infection, hemocoagulation disorders [17, 25].

From the point of time, occlusion of AV access can be divided into an early and late. The causes of an early occlusion of AV access are:

- 1) Technical errors- dissection of a vessel, narrowing of a vessel, anastomosis, sensitization of a vein during preparation and ligation of collateral.
- 2) Tactical errors- thin, inappropriate vascular system, postinflammatory changes, central vein obliteration, the disproportion between artery and vein.
- 3) Systemic causes-thrombophilia, low blood pressure, low heart output.

Late occlusion of an AV access is in 90% caused by intimal hyperplasia, then the progression of atherosclerotic changes and post-cannulation changes of the venous system.

Many techniques have been used to treat thrombosed AVF. The main condition of successful treatment is treatment not only thrombosed part of AVF but also the treatment of a cause- most frequently stenosis. Surgical thrombectomy is complicated by the presence of old, organized, and adherent part of thrombus. In cases with juxta-anastomotic stenosis is possible either correction of stenosis by surgical method or neo anastomosis proximally. Endovascular treatment is a better option, mainly in a patient with stenotic lesions far from the anastomosis. The patient with aneurysmatic AVF is indicated for resection and new anastomosis.

Aneurysm and False Aneurysm

Maturation and dilatation of the venous segment is normal finding after creation AVF. In approximately 15%, AVF is dilatation more progressive with increasing risk of complications. A cause of extreme dilatation can be stenotic lesion (before and after anastomosis), extremely high blood flow or repetitive cannulation in the same venous point. False aneurysm (Pseudoaneurysm) is frequently result of puncture damage of posterior wall of vein or infection. An aneurysm can result in thrombotic or bleeding complications. In aneurysmatic and thrombotic AVF is inevitable resect dilatated segment of AVF with inherent thrombus with new anastomosis more proximal. Aneurysmorrhaphy is the possible modality of treatment in a patient with the long dilatated venous part, without thrombotic masses. Pseudoaneurysm is more frequent in AVG, often with infection and in this cases should be all AVG removed. In cases without infection is possible option resection and implantation of new graft. The indication for a repair and treatment of aneurysm include symptomatic aneurysm, evidence of infection, and aneurysm with thromboembolic complications or insufficient blood flow due to thrombotic changes.

Venous Hypertension

The most frequent cause of venous hypertension in a dialyzed patient is stenosis or occlusion of central thoracic veins. The most frequent cause of stenosis or obliteration of central veins is the previous implantation of the catheter. Risk factors are prolonged implantation of tunneled and no tunnel catheters, repetitive cannulations of central veins and infection. Treatment of stenotic lesion may be surgical or endovascular. In cases of central venous stenosis is preferred endovascular therapy with or without stent implantation. Surgical treatment was frequently used previously, dominantly with extra-anatomic procedures.

Infection

Infection is the second most frequent cause of access loss. Infection of AVF is very rare. Early (till 30 days after the operation) infection is always localized in the anastomosis. Without treatment progress infection to the formation of the pseudoaneurysm with bleeding, or progress to rupture of the anastomosis with profuse bleeding. The most frequent cause of late (more than 30 days from an operation) infection is cannulation and infection of a hematoma. This late infection consists of 94% of all infection AVF complications. Leading etiologic agent is Gram-positive cocci, less frequently Gram-negative cocci [26].

Ischemic monomyelitic neuropathy is a rare complication, typically with the profound sensory and motoric deficit, predominantly in a patient with brachial artery inflow. Incidence is less than 1%, with immediate onset after the creation of vascular access and treatment is immediate ligation of access to prevent permanent neurologic damage.

Coronary steal syndrome can be present in a patient with a coronary bypass with internal mammary artery where AV shunt can activate retrograde blood flow in the mammary artery and cardiac ischemic symptoms.

Neuropathy as a result ischemic injury from vascular steal, mechanic compression or trauma, or due to local amyloid deposition leading to carpal tunnel syndrome can be seen rarely.

Hemodynamic Complications – Hyperfunctional AV Shunt

More than 50% of hemodialysed patients have cardiac problems. Creation of AVG or AVF causes an acute decrease in systemic vascular resistance and a secondary increase in cardiac output [27]. In a patient with heart failure and ejection fraction < 20% are bad candidates for an arteriovenous shunt, they have the highest risk of clinical aggravation and fatal outcome after AVF creation. In this group of the patient, the first option for hemodialysis is the insertion of a central venous catheter [28]. Before creation AV shunt each patient should be classified using the New York Heart Association functional classification (NYHA classes I to IV) and the American College of Cardiology Foundation/American Heart Association stages of heart failure (ACC/AHA stages A to D) [29]. Patient with stage C ACC/AHA and NYHA I-II are candidates for distal radiocephalic shunt, patients with stage C ACC/AHA and NYHA III-IV, or ACC/AHA stage D are candidates for the venous catheter. Normal flow through AV shunt, sufficient for hemodialysis is over 500ml/min. With time, the vein is more dilatated and flow through AV shunt increase and can lead to heart failure. By Vascular access society guidelines, high flow AV shunt (AVF, AVG) is defined as a flow-through shunt > 1,5l/min, and cardiopulmonary recirculation > 20% Cardiopulmonary recirculation (CPR) is a relation between shunt flow (Qa) and cardiac output(CO). Than $CPR = Qa/CO$.

Patients with AV shunt related heart failure management begins with medicament therapy of arterial hypertension, heart failure, diuretics, and by adjustment of hemodialysis for better volume control [30, 31, 32, 33]. If despite this precautions hearth failure progress, we should reduce blood flow of AV shunt and close all unused AV shunts. If this step is insufficient, we should close the AV shunt and insert a catheter for hemodialysis.

Indications to reduce blood flow on the AV access:

- 1) Heart failure + $Qa > 1600 \text{ ml/min}$ and/or $Qa/CO > 0,3$
- 2) Steal syndrome + Qa in patient with AVF $> 800 \text{ ml/min}$, + Qa in patients with AVG $> 1200 \text{ ml/min}$
- 3) Prevention of heart failure when $Qa > 2000 \text{ ml/min}$ and/or $Qa/CO > 0,3$

To correct blood flow of hyperfunctional AV shunt or correct ischemia, we have several techniques: PRAL, TRA, RUDI, DRILL, MILLER, BANDING, PAI options (see also vascular steal)

PRAL – proximal radial artery ligation. The technique to decrease blood flow in distal radiocephalic AVF. By ligation of the radial artery, just proximal from anastomosis, in patients with patent ulnar artery decrease blood flow by 1/3.

TRA- transposition of the radial artery. Complicating procedure with the preparation of whole radial artery involving transposition from the forearm to the elbow level to replace the brachial artery by the distal radial artery inflow.

Hemodynamic Complications – Vascular Steal

In approximately 20% of patients with AV shunt is reduced perfusion of a more distal extremity as a result of shunting. For severe ischemic symptoms are typical loss of sensation or weakness are occurring in 4% of patients, and they require intervention. The cause of severe ischemia can be a stenotic arterial lesion, absence of collateral flow, and creation of high- flow AV shunt in a patient with DM or PAD. Intervention prevents serious sequela of ischemia, and revascularization is impossible, AV shunt has to be ligated. PTA is effective only in patients with inflow arterial stenosis or PAD. Other options are corrective operations to decrease blood flow through AV shunt or procedures to the reduction of steal phenomena and to increase more peripheral blood supply [35, 36, 37, 38].

A most studied procedure is DRILL- Distal revascularisation-Interval ligation procedure. This procedure comprises ligation of brachial artery just below arteriovenous anastomosis and creation of brachio-brachial bypass operation, where proximal anastomosis must be minimally 10cm proximally from a. brachialis ligation for successful revascularization. The procedure can be performed as a single stage operation or staged procedure. This type of revascularisation is usable in both AVF and AVG procedures, primarily performed on the brachial artery.

Another technique to correct steal syndrome of AV shunt with primary anastomosis on the brachial artery is RUDI-Revision using distal flow procedure. The principle of this method is ligation of a venous segment of AVF and creation of a new anastomosis, with the new venous segment, transposed or translocated (distal part of v. cephalic) Distal anastomosis is on the radial artery and proximal on v.cephalica. In the absence of native veins, a graft can be used for the bypass procedure. By using the feeding artery with smaller diameter, we decrease blood flow -and we lengthen the cannulation segment of a shunt.

PAI- proximalisation of arterial inflow, this procedure converts the arterial supply of the arteriovenous access to a more proximal artery with higher capacity by using a small-caliber polytetrafluoroethylene graft as a feeder.

BANDING- a simple method to reduce blood flow of AV shunt by increasing venous resistance. 1-2cm distally from AV anastomosis is vein stitches with a cuff to reduce blood flow.

MILLER - Minimally Invasive Limited Ligation Endoluminal-assisted Revision is a modification to the traditional banding procedure, which markedly improves banding outcomes. A modified banding procedure requires a small (1-2 cm) skin incision to the place of a ligature and utilizes a 4 or 5 mm diameter endoluminal balloon to achieve the desired reduction of inflow size [39, 40, 41].

Less severe symptoms, sense of coolness and paresthesia are frequently present, and they improve in a period of weeks with a development a collateral blood flow.

Steal syndrome has four stages:

- Stage 1 – without steal
- Stage 1 – moderate steal (no therapy required, sense of coolness)
- Stage 2 – moderate steal (therapy individually indicated, intermittent ischemia, claudication)
- Stage 3 – severe steal (surgical treatment indicated, rest pain, defect)

AV Graft

In contrast to native AV fistulas, AV graft (AVG) don't need time to maturation and can be accessed for hemodialysis in short time after implantation. For hemodialysis is graft usable within 24 hours after AVG creation, but better is wait approximately two weeks to the first cannulation [42]. This period is enough for tissue ingrowth and resolution of surgical inflammation and edema. Because of a higher rate of infectious complication and a higher rate of failure in comparison to native AVF, implantation of prosthesis is indicated only in patients with no possibility to perform native AVF and in patients when it is certain, that in short time hemodialysis will be starting [43]. According to the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-KDQOI) Clinical Practice Guidelines, the preferred AVG site types are the antecubital forearm loop graft and the upper-arm curved graft. Left-right -localization depends on handedness. First AVG should be performed on the nondominant upper extremity; the lower extremity is considered when all possible sites on upper extremity are exhausted or are present stenosis or obliteration of central thoracic veins. In patients with patent and the nonstenotic central thoracic vein is one of the last options, chest wall graft [44]. In patients with type I and II of thoracic central venous obstruction are possible to perform cross – over graft implantation, to connect better arterial feeding artery (a. subclavian, a. axillaris) with the nobliterated draining venous system [45, 46].

There are many types of graft that can be used for the creation of AVG. The most frequently used graft prosthesis for AVF is polytetrafluoroethylene (PTFE) prosthesis. This prosthesis- graft is available either as a normal thickness or as a thin- wall graft. Another possibility is heparin- bounded graft or externally supported grafts. External support in this type of prosthesis provides resistance to kinking and mechanic compression. For patients that need the first hemodialysis shortly after AVG creation (in 24 hours), can be used multilayer-graft, with auto seal property. Tapered grafts with one end with a smaller diameter for arterial anastomosis, to prevent high flow related complications. To prevent venous stenosis, there are commercially available PTFE nitinol reinforced grafts with stent reinforced end inserted into outflow vein or double parts HeRO grafts with nitinol-reinforced silicone single-lumen

outflow catheter. From other grafts, we can use an allograft, xenograft, or tissue-engineered grafts. Cryopreserved allografts can be used to replace infected AVG and can be prepared from a great and short saphenous vein or brachial and cephalic veins. This cryogenics can be placed in the setting of systemic or local infection in patients with a history of repeated PTFE infections and exhaustion of vascular access sites. This cryogenics may be placed at a new site or old graft site. Advocates of the same site implantation argue by salvaging of angioaccess. From xenografts can be used bovine carotid artery, mesenteric vein or ureter as a conduit. Tissue engineering products are not commercially available.

Complications of AVG

A complication of AVG is similar to that AVF, but more frequently in AVG are an infectious complication and thrombotic complication [47, 48, 49]. Stenosis is localized in this type of AV access in the venous anastomosis, almost in 2/3 of cases. Other sites of stenosis are intragraft stenosis due to intimal hyperplasia, peripheral vein (other as veno-prothetical anastomosis) due to blood flow turbulence and central vein stenosis as a result of the previous cannulation [50, 51, 52]. Infectious complications continues to be among the leading causes of morbidity and mortality in patient with AVG and central venous access [26]. Infection account for more than 12% of all death among hemodialysed patients. Vascular access is responsible for 48–73% of all bacteremias in the hemodialysis population. Majority of this bacteremias are caused by staphylococci and is associated with a high rate of mortality and metastatic complications (septic endocarditis, arthritis, osteomyelitis...). The incidence of infection is highest in central venous catheters and higher in AVG in comparison to AVF. Postoperative wound infection or poor aseptic technique may cause infection of AVG. Actually, the majority of AVG are of PTFE material and repetitive cannulation, perigraft hematoma formation, prolonged postdialysis bleeding from graft, and poor hygienic standard of personal increase the likelihood of AVG infection. 30 day (early infection) AVG infection rate is 6%. Treatment strategy depends on signs and clinical status. Minor infection – local infection can be treated by antibiotic therapy and local measures. Abscess formation in the proximity of a graft or infection of a prosthesis should be treated more aggressively. This encompasses excision of an infected segment of PTFE, but the better option is total graft excision, because of the high rate of recurrent infection with necessity nevertheless total graft excision finally. Silent graft infection with bacteriemia and without clinical signs may be undetected.

Central Venous Access

Insertion of a central venous catheter is one of possible modality to perform hemodialysis in a patient with end-stage kidney disease. A central venous access device is defined as a catheter whose tip is located in the superior vena cava, in the right atrium, or the inferior vena cava. Access is obtained by a percutaneous puncture to cannulate the vein.

Central venous catheters are classified based on a duration of catheter use, place, and type of insertion and number of lumens. Nontunneled centrally inserted central catheters are placed percutaneously with the catheter exiting the skin in the vicinity of the venous cannulation site (jugular, subclavian, femoral). They are most commonly used for temporary

access. Tunneled central venous catheters traverse a subcutaneous tunnel between the catheterized vein and the skin exit site. They can be with or without a cuff to anchor it in place and limit bacterial entry. Cuffed, tunneled catheters are most frequently used for chronic hemodialysis procedure. Factors influencing catheter selection are the duration of venous access, number of lumens needed, and patients consideration. A common indication for the placement of a central venous catheter is no or inadequate peripheral venous access. Nontunneled central venous catheters are in place for a few days to no more than one to two weeks and are usually placed into peripheral veins of the upper extremity. Nontunneled catheters avoiding the subclavian site are used for short-term access when acute hemodialysis is indicated and are not recommended as short-term access in patients with low glomerular filtration rates (<45 ml minute, IIIb stage). Femoral catheters are used to a single dialysis session. They are composed of materials such as polyurethane, polyethylene, polyvinyl chloride, and medical-grade silicone. They are different from the point of outer diameter ranges from 8 to 13.5 French (Fr), configuration (straight, curved) and of different lengths. They are rigid with the risk of vessel trauma, with a conically pointed tip and for insertion from the left side should be used longer one. After insertion, immediate X-ray chest control should be done, exclude complications, and verify the tip catheter position.

Tunneled catheters are used for acute and also for chronic dialysis. They are a good option for a patient with bad vascular access to patients with a suitable vascular bed for arteriovenous anastomosis. Even for a patient with acute renal failure are tunneled catheters better with a lower rate of infection complications in comparison with notunneled catheters. With tunneled cuffed catheter patient can leave hospital and tissue ingrowth into the cuff and prevent malposition of a catheter. Cuff is localized in a subcutaneous tissue between skin and vein entrance points. Quality of dialysis is also better with cuffed tunneled catheters, that allows higher blood flow in comparison to non-tunneled catheters. A typical tunneled catheter is curved, double lumen and with cuff.

Central Venous Catheter-Related Complications

Infection is more frequently present in notunneled catheters compared to tunneled catheters. Tissue ingrowth and cuff in tunneled catheters reduce the risk of infectious complications. Femoral catheters are more susceptible to infection than thoracic catheters. Infection may originate from the skin of patients with migration along with the catheter, poor personal hygiene, hematogenous spread from other sites. In tunneled catheters, infection external to the cuff is classified as exit site infection, whereas infection that extends in the tunnel proximal to the cuff are labeled as tunnel infections. Tunnel infection is frequently associated with bacteremia. Poor hygiene and DM are a risk factor for exit site infection. Treatment relates to the antibiotic therapy and removal of a catheter and replaces by a new one at the new venotomy place [53, 54, 55, 56, 57].

Vein stenosis/Thrombosis. After cannulation of a vein, in the site of vein trauma starts healing, which leads to the fibrillization and sterilization of a vein. Repeated cannulation at the same point leads to the reinjures. Another place of a vein trauma and possible point of stenosis is a part of vein repetitively chafed by a tip catheter and also turbulent blood flow beyond the tip of a catheter which stimulates endothelial proliferation. Vein thrombosis and stenosis are frequently present in subclavian rather than jugular catheters. Most central venous stenosis is asymptomatic and starts to be symptomatic after the creation of a

peripheral, ipsilateral AV access. Symptoms of central stenosis/thrombosis depend on the extension of stenosis or thrombosis and collateral circulation. Central vein thrombosis responds to anticoagulation and thrombolytic therapy with consecutive angioplasty, eventually implantation of stents/stent grafts [58, 59].

Catheter malfunction when blood/saline cannot be drawn from a catheter or saline cannot be infused into catheter, causes are mechanical (kinking, the tip of a catheter pushed against the wall), thrombotic (external or internal thrombosis) (Table 3).

Table 3. Types of a catheter-related thrombus

Intrinsic thrombus	Extrinsic thrombus
Intraluminal thrombus- thrombus inside of a catheter	Central vein thrombus- catheter with complete thrombosis of a vein
Tip thrombus- thrombus in the tip of a catheter	Mural thrombus- thrombus on the wall of a vein in a place of its contact with a tip of a catheter
Sheath thrombus- thrombus as a part of a sleeve around a catheter	Atrial thrombus- thrombus in a right atrium

Malfunction of a catheter, from the point of timing, is early or late. Malfunction immediately after implantation means, that catheter never functioned adequately. This is a technical problem and after retracting should be placed in a correct position. The most frequent cause of late dysfunction, previously working adequately, are thrombotic complications (Table 3). When symptomatic thrombosis is present, the catheter should be removed and a new one inserted. In patients with extrinsic thrombosis, the catheter should be extracted, starting anticoagulation therapy and in the presence of big atrial thrombus surgically removed.

CHRONIC VENOUS INSUFFICIENCY AND VENOUS SURGERY

Duplex ultrasonography is the most frequently used modality to evaluate lower extremity chronic venous disorders encompass a large spectrum of morphologic and functional abnormalities of the venous system. They can present in childhood as congenital lesions or acquired disorders that by adulthood are quite common.

Veins of the lower extremity consist of superficial and deep systems joined by venous perforators. The saphenofemoral junction is marked by branches of the greater saphenous vein, circumflex iliac vein, the external pudendal vein, the superficial epigastric vein, and the medial and lateral accessory saphenous veins. Deep veins of the leg lie in the courses of the arteries. Two or three venous concomitants accompany each tibial artery. Knowledge of lower extremity venous anatomy is inevitable in understanding the physiology of venous flow.

Anatomy, Physiology, and Pathophysiology of the Venous System

The anatomy of the veins of the lower limbs is hugely variable, but there is order in the variability. The veins of the lower extremities are divided into three systems: the superficial, the deep, and the perforating (vv.perforantes) venous systems.

Superficial veins drain the area between the skin and muscles fascia, carrying blood to the deep venous system. The saphenofemoral junction is an essential part of the function of the venous system during deep venous thrombosis and in the treatment of varicosities. The main trunks of the superficial venous system are greater and lesser saphenous veins.

Deep veins are located close to the arteries. Perforating veins perforate the muscular fascia to connect superficially with deep venous systems. The important perforating vein is the Cockett's (medial ankle), Boyd's (proximal medial calf) and Dodd's (medial upper leg). In the standard limb, the perforating veins permit the unidirectional flow of blood from the superficial to the deep venous systems through a set of one-way valves. Perforating veins are either direct- permitting the superficial venous system to communicate directly with main deep veins or indirect- such that they connect with the deep veins by way of muscular veins.

Communicating veins (collateral veins, tributary veins) are veins that interconnect with veins of the same system.

The lower limb veins below ligament contain valves in their lumen and along their entire length that allow blood flow only from the periphery to the heart against the force of gravity. The tone of the veins, arteriovenous coupling (transfer of a pulse from artery to a neighboring vein) accompanied by the suction effect of the heart and thoracoabdominal pump function of breathing helps in this process. This, in combination with competent venous valves, guarantees blood flow to the heart by muscle contraction.

Disruption of the venous blood flow plays a key role in venous disease progression. This can be caused by incompetence of venous valves (primary – inherited, secondary- acquired) acute or chronic occlusion of a vein, increase of resistance to blood flow (e.g., stenosis), or any combination of these abnormalities. These abnormalities stepwisely progress to the state of continuous venous hypertension of the lower limb with a wide variety of symptoms and signs.

The state of continuous venous hypertension of the lower limb is described as a Chronic venous insufficiency (CVI). Signs of CVI may be present in the form of heavy leg, pain, hyper or depigmentation of the skin, eczematoid dermatitis, and other skin changes. The typical changes of the skin are divided into 1- corona phlebectatica: dilatation of venules of the foot and edema, 2- stasis eczema: hyper or depigmentation of the skin, 3- florid and healed cutaneous ulceration.

Leg pain is the commonest complaint in venous disease, and its chronic nature means that it impacts significantly on patient's quality of life. Venous pain is frequently associated with other unpleasant sensations like a feeling of heaviness, cramps, the tension in the legs, pruritus. The intensity of the pain is not correlated with the severity of the venous disease, and many patients with venous pain have no objective clinical or paraclinical abnormalities. The likely trigger for this pain is hypoxia caused by venous stasis, with local inflammatory reaction and activation of nociceptors in the vein wall.

Swelling- edema is an early symptom of venous disease. Usually, edema is mild and limited to the area just above the shoe line around malleolar and resolves with bed rest and after the limb has been elevated. With more advanced varicose veins the edema progress up to the mid-calf region and normally pitting edema progress to chronic edema with subcutaneous fibrosis and then edema fail to pit.

A VEIN-TERM consensus of an American Venous Forum (AVF), the European Venous Forum (EVF), the International Union of Phlebology (IUP), the American College of Phlebology (ACP), and the International Union of Angiology (IUA) standardize venous nomenclature:

Chronic venous disorder- the full spectrum of morphological and functional abnormalities of a venous system.

Chronic venous disease- when morphological and functional abnormalities of long duration are manifested by signs and symptoms indicating the need for treatment and further investigation.

Chronic venous insufficiency- describe patients with the chronic venous disease who display more advanced clinical signs, such as significant edema, skin changes, or ulceration.

Diagnostic Steps of Investigation

The physical examination may play an important role in guiding therapy. The patient's limb is inspected in a standing position. The presence of the ankle venous flare underneath the medial malleolus is one of the first signs of CVI. Telangiectasias are defined as dilated intradermal venules less than 1 mm in size; reticular veins are dilated, subdermal, non-palpable veins 3mm or less in size and varicose veins are dilated, palpable, subcutaneous veins larger than 3 mm. Edema indicates more advanced venous disease. The presence of skin changes or venous ulcer should be described with its size and depth.

Classification of truncal varicosity of greater saphenous vein, as described by Hach, is divided into four groups: I- saphenofemoral incompetence, II- varicosity between the groin and upper calf, III- varicosity from saphenofemoral junction to proximal lower extremity and IV – varicosity of the entire great saphenous vein.

In all patients with varicose veins, the extent of damage to superficial and deep veins should be described by clinical examination and by Duplex Ultrasonography. The traditional functional tests (Perthes, Trendelenburg, Tourniquet) are seldom used, and phlebography is reserved only for more complex cases (e.g., valve vein surgery).

Venous system for the management of CVI. The duplex ultrasound examination should demonstrate the anatomic patterns of veins and abnormalities of venous blood flow in the limbs. By ultrasound should be determined incompetent greater and lesser saphenous vein, the extent of reflux, other relevant veins that show reflux or the source of filling of all superficial varicose veins and the state of the deep venous system.

Venous reflux is defined as retrograde flow in the reverse direction to physiological flow lasting for more than 0,5 s.

Because of its reliability, the use of Duplex scanning in combination with a functional hemodynamic measurement technique is accepted as the preoperative standard diagnostic procedure.

Varicose Veins

- Dilated, tortuous superficially passed veins in the lower extremities, usually bilateral
- Asymptomatic or as a symptomatic may be associated with localized pain, nocturnal cramps
- Pigmentation, ulceration, and edema suggest concomitant venous stasis disease
- Increased frequency after pregnancy

Varicose veins are very common, afflicting 10-20% of the world's population and are more than 3 mm thick. They involve great and small saphenous vein, saphenous tributaries, or nosaphenous superficial tributaries. Mainly they are accompanied by reflux in the venous system, but they can also be as isolated varicosities. Abnormally dilated veins occur in different locations in the body. Varicosities of the legs were firstly described in 1550 BC. They are primary or secondary. Many varicose veins are asymptomatic and are an only aesthetic problem. If symptomatic may be associated with localized pain, burning sensation, a diffuse ache or heaviness in the calf or phlebitis. The varicosities are dilated, tortuous, elongated veins predominantly on the medial aspect of the lower extremity. A complication of varicose veins includes thrombosis and bleeding with the need for conservative and invasive therapy.

Classification

CEAP classification is used for chronic venous insufficiency (CVI). C means clinical presentation, E means etiology, A means anatomy, and P means pathophysiology. In clinical praxis is the most used C like Clinical presentation. E, A, P are used not so often.

C-Clinical Presentation

No visible or palpable signs of venous disease (C0) - patient with or without difficulties.

Telangiectasias/reticular veins (C1) are small skin and sub-skin vessels in diameter < 1 mm (teleangiectasia or spider veins) or < 3-4 mm. They are normally visible, mainly in persons with thin, transparent skin.

Varicose veins (C2) are subcutaneous vein with a diameter over 3-4mm and are frequently tortuous. They can involve main venous trunks (great and short saphenous vein), their tributaries, or collateral superficial leg veins.

Edema (C3) is due to the increased volume of fluid in sub-skin tissue and skin.

Pigmentation or eczema (C4a) Pigmentation is caused by hemosiderin deposits in the skin as a result of extravasation of red cells. They are localized below the knee, with maximal localization in the ankle region. Eczema is caused by venous disease, but not always accompanied by varices.

Lipodermatosclerosis (4b) trophic changes of skin and sub-skin tissue due to venous hypertension. Diffuse chronic inflammation, followed by fibrosis and scarring any color changes of the skin. Atrophia Blanche is localized white change surrounded by dilated capillaries and by hyperpigmentation.

Healed venous ulcer (C5) typically localized in the medial part of a calf with other clinical symptoms of CVI around.

Active venous ulcer (C6) defect of skin in an ankle or calf. The depth and area is very varied, and the healing process is complicated, mainly in ulcers with a long history.

E-Etiology

Congenital (Ec) congenital vascular abnormalities from birth or developed later during life.

Primary (Ep) from different causes, mainly from reflux in truncal veins.

Secondary (Es) secondary venous disorders, most frequently from trauma and thrombosis.

A-Anatomy

Superficial venous system (As) contains vein between fascia and skin. The major veins are great short saphenous veins and their accessory veins.

Perforating veins (Ap) connect the deep and superficial venous system. They can be divided into direct and indirect veins. Direct communicating veins, frequently located medially in the thigh and calf and they could be the cause of primary and recurrent varicose veins.

Deep venous system (Ad) veins bounded by muscle fascia. They are intramuscular and intermuscular. The intermuscular are more important in the development of chronic venous disease. The intermuscular veins include the popliteal vein, crural veins, femoral common, deep veins.

Anatomy not specified (An) if an anatomic location is not identified.

P-Pathophysiology

Venous reflux (Pr) is abnormal, retrograde blood flow through the venous segment. The valves are damaged by trauma or thrombosis, or by congenital valvular abnormalities. Reflux can be localized in superficial, deep or perforating veins, local or in the entire venous trunk. Reflux in a deep venous system is associated with more ulcers defect in comparison to reflux in the superficial venous system, but ulceration is also possible as a result of superficial venous reflux.

Venous obstruction (Po) that impedes blood flow. Over time thrombus remains as a scar or is spontaneously resorbed (partially or totally), and the venous segment is without functional valves, that results in reflux.

Venous reflux and obstruction (Pr,o) when both entities are present.

Reflux not specified (Pn) when neither reflux nor obstruction is identified.

Corona phlebectatica as a no part of CEAP classification, are small intradermal veins, localized in medial or lateral ankle. More frequently present in patients with reflux.

Klippel- Trenaunay syndrome is congenital disorder and is characterized by the presence of varicosities (venous malformation), capillary malformations, limb overgrowth, and possible lymphatic anomalies.

Clinical Severity

There are several measurement tools that help to objectively follow patient response to clinical management. Venous clinical severity score (VCSS) from ten clinical parameters that are graded from zero to three depending upon severity classify severity disease, like CEAP classification.

Table 4. VCSS score (every parameter has a maximum of three points)

Pain or discomfort of presumed venous origin
Varicose veins ≥ 3 mm in standing
Venous edema
Pigmentation
Inflammation: Erythema related to cellulitis, dermatitis or venous eczema
Induration
Number of active ulcers
Duration of active ulcers
Size of active ulcers
Compression therapy

Venous disability score (VDC) quantifies physical problems due to CVI (Table 5.)

Table 5. Venous disability score

score	symptoms
0	asymptomatic
1	asymptomatic: usual daily activities without compression therapy
2	symptomatic: usual daily activities with compression therapy or elevated legs
3	symptomatic: unable to carry out daily activities even with compression or elevated legs

Venous segmental disease score (VSDS) grades major venous segments according to the presence of reflux and obstruction. Each anatomic segment is weighted with points to maximum 10points for reflux and 10 points for obstruction (Tables 6,7).

Table 6. Points of VSDS for reflux (to total point count either a posterior tibial vein or more than 2 of calf veins)

points	venous segment		points
	tight	calf	
0,5	small saphenous vein	posterior tibial vein	1
1	great saphenous vein	more than 2 of calf veins	2
0,5	perforator, tight	perforator, calf	1
2	popliteal vein		
1	femoral vein		
1	deep femoral vein		
1	The common femoral vein or above		

Table 7. Points of VSDS for obstruction

points	venous segment
1	great saphenous vein
1	calf veins multiple
2	popliteal vein
1	femoral vein
1	deep femoral vein
2	common femoral vein
1	iliac vein
1	inferior vena cava

Table 8. Villalta score (points: 5-9 Mild, 10-14 moderate, 15-48 severe, points less than four not present)

symptoms	clinical signs
pain	pretibial edema
cramps	skin induration
heaviness	hyperpigmentation
paresthesia	redness
pruritus	venous ectasia
	pain on calf compression
	+ venous ulcer: present 15 pts, absent 0 pts

Villalta scale for patients with the postthrombotic syndrome. Helps identify and treat patients in the early stages of the disease. Symptoms and clinical signs are calculated depending on their severity (none:0, mild:1, moderate:2, severe:3). Total points count over 15 indicates a patient with severe postthrombotic difficulties (Table 8).

Aberdeen Varicose Vein Questionnaire (AVVQ) as a tool is acceptable to patients and could be used as a guide for referral for specialist varicose vein assessment. The questionnaire consists of 13 questions (7 questions for both lower extremities), from this one diagram (question 1) where patient draw the location of their varicose veins. Total score results are from zero to 100, with zero representing the best score, and 100 the worst one. The modification and conversion of the AVVQ into an electronic version should ease the adoption of this tool at home and possibly the reduced expense and inconvenience of unnecessary appointments when they were not eligible for Health systems funded treatment.

Charing Cross venous ulcer questionnaire (CCVUQ) was developed to provide a valid quality-of-life measure for patients with venous ulcers.

Treatment

Treatment for varicose veins can be divided into two categories: conservative therapy: medical and compression therapy and interventional therapy: surgical procedure, sclerotherapy, and endovenous ablation.

Nonsurgical Therapy

Compression therapy of the lower leg is an effective intervention and cornerstone in the prevention and treatment of venous and lymphatic diseases. Compression therapy prevents edema and accelerate of the venous blood flow and is especially essential when ulcer cruris is present. Medical compression therapy includes static and dynamic mechanical compression provided by garments and different devices [60].

Static compression includes hosiery and bandages, in dynamic compression, we use a different form of pumps and sleeves. Static compression therapy is characterized by a constant pressure gradient of a sleeve or bandage against extremity. This pressure gradient increases deep vein flow velocity and venous return, improve microcirculation, improve lymphatic drainage, and decrease venous pressure. This compression also reduces the extent

of edema, lipodermatosclerosis, pain, skin changes, and helps in an ulcer healing [61]. Many studies showed a benefit action of compression therapy for ulcer healing and showed more than 97% healing rate in patient compliant for therapy, where this therapy decrease inflammation and expression and activation of metalloproteases and increase the healing rate and reduction of ulcer.

Compression hosiery for treating symptoms of CVI are available in four compression grades. To prevent exudation of fluids from vessels, to inhibit symptoms of severe CVI, the pressure gradient in an ankle region should be more than 35-40 mmHg. For more severe grades of CVI are indicated high-grade pressure stockings. Extra firm stocking, with compression pressure over 40mmHg, is reserved for patients with lymphedema (Table 9).

Table 9. Types of stockings in CVI

Class	Pressure (mmHg)	Indication
I	15 – 20	minor varicosities, tired aching legs, swelling of ankle and foot
II	20 - 30	moderate varicosities and swelling, phlebitis, after ablation
III	30 - 40	severe varicosities and swelling, post-DVT, active ulcer
IV	>40	lymphedema

Length of stocking varies from knee-high, tight-high to pantyhose stocking. Type of stocking, from the point of length view, depends on the proximal point of reflux. Stocking should compress this region too. In the absence of reflux, the length of a prescribed stocking depends on patient preference [62]. The spike of stocking can be open or closed. There are also some custom products; the most favorable are zippered stockings, used mainly by patients who don't have strength or mobility to pull on stocking. In this, pulling on, the maneuver can be helpful, donner (wireframe or tube-like sleeve), butter or silk hose under the high-grade pressure stocking.

Dynamic compression or intermittent compression and is usable in patients who don't tolerate static compression. The device consists of a single chamber or multi chambers, which inflate sequentially from foot to the knee and thigh.

Contraindication of compression therapy is PAO, heart failure, and acute cellulitis, infection, skin necrosis.

Medical therapy with the vasoactive drug has been shown to increase venous tone and improve venous and lymphatic drainage. Venoactive drugs are prescribed mainly to improve edema and symptoms, and the most commonly used are flavonoids, more particularly, micronized flavonoids. They increase venous tone by inhibiting noradrenalin breakdown by catechol-O-methyltransferase to prolong noradrenergic activity. They protect microvascular permeability by inhibiting adhesion and migration of leukocytes, production of inflammatory, leukocyte and endothelial mediators (L-selectin, ICAM-1, VCAM-1) [63]. They increase lymphatic drainage and peristalsis of lymphatic veins and decrease capillary permeability. Another positive effect is reduced aggregation of leukocytes, local inflammatory process, and their migration into the vein wall. By limiting red cell aggregation, they decrease blood viscosity and increase blood velocity. Moreover, finally, they facilitate fibrinolysis.

Pharmacologic therapy can be categorized as venoactive drugs and rheologic drugs. Venoactive drugs are of a plant origin and synthetic origins (Table 10).

Table 10. Types of venoactive drugs

Origin	Drugs
Plant	Gamabenzopyrones – Flavonoids (Diosmin, Hesperidin) Rutosides (rutin, troxerutin) Alfabenzopyrones - coumarins Saponins – horse chestnut seed extract, Ruscus aculeus extract (Aescin) Other: anthocyanins, proanthocyanidins- grape seed extract, red wine leaf extract, ginkgo balboa extract, Centella asiatica extract
Synthetic	Calcium dobesilat, Naftazone, Tribenozid, Benzarone

The alpha-benzopyrone coumarin has been used either alone or in combination with other drugs for the treatment of lymphedema, and several studies have reported favorable results, but its hepatotoxicity has dramatically limited the use of coumarin. Flavonoids inhibit leukocyte activation, adhesion, and migration and modify leukocyte-endothelial interactions, inhibiting the expression of intercellular adhesion molecules (ICAM-1) and vascular adhesion molecules, and prevent endothelial damage. Rutosides are indicated as an antiedematous agent in venous disorders by increasing venous tone by blocking inactivation of noradrenaline, reduce the symptoms of venous disease, particularly swelling, and improve hemodynamic venous function. After the admission of a Naftazone venoconstrictor effect and lowering of serum beta-glucuronidase levels was seen and it acts on vessel wall permeability and on abnormalities of endothelial cells. Tribenoside decreases capillary permeability and has anti-inflammatory and analgesic actions [64]. Calcium dobesilate decreases capillary permeability and blood viscosity and improves lymphatic drainage. Benzarone has fibrinolytic properties and inhibits platelet aggregation.

Rheologic drugs affect the flow properties of blood. Aspirin and Pentoxifylline accelerate healing of venous ulcers. Stanazolol- oral steroid- stimulates blood fibrinolysis and helps with improvement in the area of lipodermatosclerosis, reduced skin thickness, and possibly faster ulcer healing. Prostacyclin is a potent vasodilator inhibits platelet aggregation, and adhesion increases red blood cell deformability, alters neutrophil function (including free radical production) and capillary permeability, and may help repair damaged endothelium. Sulodexide has antithrombotic and profibrinolytic activity related to its affinity for antithrombin III and heparin cofactor II and effects on leukocyte-platelet activation and has antithrombotic, profibrinolytic, and fibrinogen-lowering properties too.

Surgical Treatment

Surgical removal of varicose veins is often for cosmetic reasons. Noncosmetic indications include symptomatic varicosities, or the treatment of venous hypertension with skin or subcutaneous tissue changes, such as lipodermatosclerosis, atrophy blanche, ulceration, or hyperpigmentation have developed.

The indication for surgery is largely based on patient preference. Choice of treatment is the also affected by symptoms, cost, available medical resources, insurance reimbursement and physical training as well as the presence or absence of deep venous insufficiency, the characteristics of the affected vein and potential for iatrogenic complications.

In primary varicosity (genetic) is surgical therapy indicated for saphenous, perforating, and branch vein varicosities [65]. In secondary varicosities (e.g., postthrombotic) the decision on surgical therapy has to be made carefully, and sufficient blood flow has to be ensured from lower extremity to the heart after surgery.

The treatment aims are to ablate reflux from deep system to superficial. This is in 70% of cases reflux from femoral vein to greater saphenous vein, so-called saphenofemoral reflux. In 20% we can see reflux from popliteal vein to lesser saphenous vein, so-called popliteoparval reflux. In 10% of cases, it is reflux from the deep system to the superficial system through perforators. Indications for surgical treatment include pain, that can be persistent or disabling, erosion of the overlying skin with bleeding, recurrent superficial thrombophlebitis, and manifestations of chronic venous insufficiency (particularly ulceration). In patients with an incompetent valve at the saphenofemoral junction, high ligation and stripping of the saphenous system are performed [66]. Today, the saphenous vein can also be ablated by either radiofrequency ablation (RFA) or endovenous laser treatment (EVLT).

Standard Varicose Vein Surgery

Standard varicose vein surgery remains the gold standard of therapy and involves ligation and disconnection of the great and small saphenous at their junction with the deep venous system. Ligation of the great saphenous vein involves tying off the vessel at the saphenofemoral junction accompanied by stripping of the great saphenous vein. Ligation alone, without stripping of the vein is associated with a high varicose vein recurrence. After ligation of great saphenous vein and tributary veins, the saphenous vein is tied to the tip of a stripper, and the vein with a stripper is pulled down through small incision. Stripping first of all requires that a stripper be passed into the saphenous vein [67]. The site of a small distal incision depends on a type of truncal varicosity as described by Hach (see above) if the stripper is inserted upwards. When the saphenous vein is insufficient along its whole length, a small distal incision is located at the ankle – total stripping of a vein. Stripping to the knee (partial stripping) reduces the risk of saphenous nerve injury.

Figure 1. Classical stripping of an SSV- stripper inside an SSV.

Another possibility of stripping is when the stripper is inserted downwards (from the groin into a saphenous vein), but there is a risk of the head of the stripper entering saphenous collateral.

For short saphenous vein is recommended limited stripping of the vein to the mid-calf, because of possible injury to the sural nerve. (Picture.1) The proximal, small transverse incision in the knee crease is located about 3 to 5 cm distal to the saphenopopliteal junction and with stripping using the same techniques as described for the great saphenous vein.

A complication of a surgical procedure includes hematoma, postoperative bleeding, infection, nerve injury, thrombosis, lymph leak [68]. The risk of recanalization with open surgery is zero, enlargement of other veins in the extremity can occur over time. Recurrence rates of surgical technique are associated with varicose vein between 20 and 28 percent.

Phlebectomy

Phlebectomy involves removing abnormal veins, not including saphenous veins. Under local anesthetic – outpatient procedure- small incision are made in the skin, and large varicose veins are removed using phlebotomy hook. This procedure is well tolerated, and complications are rare, but recurrence is high if the source of the reflux is not treated. If present, reflux should be abolished by some method (standard surgery – see above, endovenous procedures – see below) and phlebectomy is adjuvant to saphenous vein surgery [68].

Transilluminated powered phlebectomy (TIPP) is an alternative to traditional phlebectomy. During the procedure, an endoscopic transilluminator is inserted beneath the skin to illuminate the vein cluster that needs to be resected. A suction device with guarded blades (resector) is then introduced via another incision at the other end of the varicose vein, and the veins are cut and removed by suction [69]. This techniques has the proposed advantages of decreasing the number of incisions and reducing operative time.

Endovenous Procedures

In the last decade, endovenous ablation procedures have become a frequently used therapy for saphenous varicose veins. The endovenous thermal ablation techniques currently available are: endovenous laser ablation, radiofrequency ablation, and endovenous steam ablation. All endovenous techniques act by destroying the inner lining of the vein allowing the vein to seal off and turn into fibrous tissue, which is gradually removed by the body [71]. Endovenous procedures are recommended for great saphenous vein, short saphenous vein, accessory saphenous veins, Giacomini vein and cranial extension of a short saphenous vein, other superficial veins situated in the subcutaneous tissue, insufficient perforating veins, residual intrafascial veins after treatment and some of the venous malformations. Specific requirements for the segmental radiofrequency method is at least 10cm vein segment or 5 cm segment of a vein if a shorter heating element is used. For incompetent perforating veins, we need special radiofrequency stylet device, or for endovenous laser, there are no such restrictions. In veins that contain synechia/membrane webs/postthrombotic changes the use of a special guide-wires, manual maneuvers or multiple entry sites are necessary. Absolute contraindications of endovenous procedures are acute deep vein thrombosis, acute superficial phlebitis, acute infections at the puncture sites, and deep venous obstruction if the vein to be treated is functional collateral. Relative contraindications are: immobile or hardly ambulating

patient, significant peripheral arterial disease with ankle-brachial index $>0,5$, pregnancy, elevated thromboembolic risk- thromboprophylaxis should be considered, significant uncompensated leg edema which cannot be adequately monitored by ultrasound for thrombosis and allergy to local anesthetics- tumescence without local agent or another agent should be used. Relative contraindications from a local point of view are tortuous vein difficult to catheterize, the diameter of a vein at the accessing segment $< 3\text{mm}$, partly occluded venous segment and vein segment to be treated shorter than necessary for catheter placement [73].

Endovenous Laser Ablation

Endovenous laser treatment (ELVES, EVLA) treats varicose veins using an optical fiber that is inserted into the vein. Then laser light, normally in the infrared portion of the spectrum, shines into the interior of the vein (Figure 2). This causes shrinking of a vein, and the optical fiber is slowly withdrawn. Minor complications can occur, as thrombophlebitis, pain, hematoma, edema, and infection [74].

During the procedure, a catheter bearing a laser fiber is inserted under US guidance into the great or short saphenous vein, small saphenous vein through a small puncture by puncturing with a 16F or 18F needle. Then guidewire is passed through the needle into the vein up to the level of the junction with the deep venous system, the needle is removed, and through a small cutaneous incision of 3 mm, an introducer sheath is placed over the guide wire and is positioned a few centimeters below the junction. Subsequently, the laser is introduced after removing the guide wire. The catheter is then placed, also under ultrasound guidance, to the level of the groin in GSV insufficiency, or knee position in SSV insufficiency. A local anesthetic is injected around the vein (tumescence) using the US to give the local anesthetic solution around the vein, in full length of the treated vein. The laser is activated while the catheter or laser fiber is slowly withdrawn, resulting in obliteration of the saphenous vein along its entire length. The leg is bandaged after the procedure. Immediately after procedures can patient leave an ambulance [75, 81].

Figure 2. ELVES 1470 nm catheter just before completion of a procedure (lights indicated a tip of a catheter, sheath already pulled out).

Many medical laser systems for vein ablation use a 980 nm wavelength, but the top is a system uses a 1470 nm wavelength, which has greater absorption by water, blood and soft tissue in the vein wall. With radial fiber that reflects the laser beam using a prism and the laser energy is emitted in 360- degree manner, thus allowing homogenous irradiation of the vein wall and making it possible to prevent perforation [76, 82].

Endovenous Radiofrequency Procedure

Several systems for radiofrequency ablation exist VNUS Closure Fast (segmental RFA) and radiofrequency-induced thermotherapy (RFITT). Segmental RFA is currently more popular method (Figure 3).

Segmental RFA has a 7 cm therapeutic distal segment that heats to 120°C. Similar to endovenous laser therapy, perivenous tumescent anesthesia is applied to optimize surface contact and to decrease pain and risk of dysesthesia. External compression enhances contact of the catheter with the vein wall. During the procedure, a small incision is made, like in laser ablation for catheter insertion. The catheter delivers energy to the wall of the vein and cause of a vein to seal it, and blood can no longer travel through it. The vein can be absorbed into the bloodstream. After the damaged veins have been sealed, blood is naturally re-routed through healthier veins in the body. Compressive bandages or medical elastic stockings are indicated for one week after treatment [77, 83].

Endovenous radiofrequency is a minimally invasive treatment modality. It's alternative to stripping in the treatment of varicose veins and offers patients effective results with less pain, bleeding, and shorter recovery times than traditional procedures. This procedure can be performed for cosmetic or medical purposes, depending on each patient's condition and goals for treatment.

Figure 3. Just prior Radiofrequency catheter insertion. (sheat inserted inside of GSV).

Endovenous Steam Procedure

Endovenous steam ablation is another method of thermal vein ablation. It works with steam to a maximum temperature of 120°C. Under the US control vein is punctured with a 16-gauge needle. After puncturing the vein, the steam catheter is passed through the hollow

needle into the vein, and positioned 3 cm from the junction, under ultrasound guidance. Tumescence anesthesia is administered into the perivenous space to reduce pain, cool the perivenous tissue, and to decrease venous diameter. After activation, the catheter releases small “puffs” of steam and is pulled back in a stepwise fashion. At the first activation, 3 cm below the saphenofemoral or saphenopopliteal junction, four puffs of steam should be administered, while exerting gentle manual pressure on the junction. Further along the vein, two or three puffs of steam can be applied at 1 cm intervals depending on vein diameter. After the procedure, patients wear medical elastic compression and to mobilize immediately after the treatment.

All of these three above mentioned procedures are tumescent procedures. They are performed under local tumescent anesthesia, without the need for general or spinal anesthesia. Tumescence anesthesia reduces pain, cools perivenous tissue, and decreases the venous diameter. During tumescent anesthesia is a large volume of very dilute lidocaine (or another anesthetic) infiltrated around a vein, with the inserted catheter by the thin needle. The tumescent solution makes a shrinking of a vein around a catheter and sets apart nerves [78, 87].

One of the possible complications after thermal ablation techniques is an endovenous heat-induced thrombosis (EHIT) (Table 11).

Table 11. Types of EHIT

Type	Localization
I	Thrombus below superficial epigastric vein
II	Thrombus up to the origin of superficial epigastric vein
III	Thrombus up to, but not into the common femoral vein
IV	Thrombus bulging into the common femoral vein, but no adherent
V	Thrombus extending into common femoral vein and adherent to the wall
VI	Thrombotic occlusion of a common femoral vein

EHIT I or II is identified, serial duplex imaging weekly with observation should be performed until thrombus regression into a superficial vein is noted. Antiplatelet therapy may be initiated in case of EHIT II. If EHIT III or IV is identified on duplex scan, low molecular weight heparin is initiated and continued, along with weekly duplex imaging and evaluation, until thrombus regression. Other possible complications include nerve injuries, bruising/hematoma, skin burns, superficial and deep venous thrombosis.

Other possibilities of vein destroying are mechanicochemical and chemical methods. These methods are not tumescent and nonthermal, and they are performed without tumescent anesthesia (except local anesthesia – puncture site of the vein – insertion of a catheter).

MOCA: Mechanochemical Ablation

The catheter (Clarivein) consists of two components - a wire rotating at high speed that damages the inner lining combined with injection of liquid sclerosant to complete venous occlusion. This mechanical-chemical ablation technique is unique. This venous ablation technique employs a hybrid (dual-injury) technique built into one catheter-based delivery

system. Endomechanical abrasion of the vessel is produced by the tip of the catheter's rotating wire (mechanical component), and endovenous chemical ablation is induced simultaneously by the injection of a sclerosant drug sprayed from the tip of the catheter as it is pulled back [80, 86]. The combination is a very efficient and painless way to seal the vein. Catheter generates no heat. There is absolutely no risk of thermal injury and no need for the use of tumescent anesthetic.

Figure 4. Clarivein in GSV.

Chemical Methods

The VenaSeal closure system is the non-tumescent, non-thermal, non-sclerosant procedure that uses a proprietary medical adhesive delivered endovenously to close the vein. After the vein is accessed, the catheter is inserted into the vein, and the tip of a catheter under ultrasound guidance 5 cm away from the sapheno-venous junction positioned. A clinician conducts a series of trigger pulls to deliver the medical adhesive. Through the catheter, the adhesive – cyanoacrylate - is given to the diseased vein that needs treatment. Just as with other vein treatment, blood is then rerouted to other healthy veins. The obliterated vein will undergo a process of hardening, sclerosis, and will be gradually absorbed by the body. Unlike other vein treatments, you will not be required to wear compression stockings after treatment.

After all endovenous techniques, very rarely, but the potential complication is an anatomic failure of a procedure. Clinical failure, in contrast to an anatomic failure, means recurrent clinical symptoms and/or varicose veins. Anatomic failure means persisting or recurrence of reflux after the procedure (Table 12).

Table 12. Types of failure after endovenous procedures

Type	Definition
I – non-occlusion	veins that failed to occlude initially and never occlude during follow-up
II - recanalization	veins that were initially confirmed to be occluded but later recanalized, either partially or completely
III - groin reflux	situation in which the vein trunk was occluded but reflux persisted in the groin region. This type of failure often involves an ASV.

Varicose vein recurrence is reported with long-term follow-up at rates that are in extensive retrospective studies between 7 to 14 percent of patients. Other complications of ablative methods include hematomas/bruising, phlebitis reaction, deep and superficial venous thrombosis, thermal damage of skin and surrounding tissue and nerves in thermal methods.

Sclerotherapy

Telangiectasia, reticular veins, and varicose veins are visible signs of venous disease and can also occur in the absence of another symptom of a venous disorder [84]. Sclerotherapy is indicated in patients, to treat symptoms and signs of venous disorders, or for esthetic reasons. By these techniques is possible also treat truncal veins with reflux and perforators. Sclerotherapy can be performed in all stages of CVI, and the patient may be either symptomatic or asymptomatic from symptoms of CVI or because of cosmetic reasons. Also, patients with bleeding complications and with stigmata of recent bleeding may benefit from sclerotherapy. Absolute contraindication to the procedure is acute thrombosis or phlebitis and allergy to liquid. It should also be avoided in pregnant women/breastfeeding. A relative contraindication is patients with PAO and DM due to micro- macroangiopathy. Increased risk of postprocedural thrombotic complications is in patients with thrombophilia and inability to mobilize. A history of migraine headache and patent foramen ovale carry a higher risk due to microembolisation.

Sclerosant can be divided into three groups: osmotic agents, detergents, and corrosive/irritant.

Osmotic agents destroy the vessel by dehydration and disruption of the cell wall. The agent is rapidly diluted, and the effect is typically localized, and systemic toxicity is minimal. However, they cause pain during injection and local damage if they are extravasated. The most commonly used are hypertonic saline (23,4%) and a combination of dextrose with hypertonic saline.

Detergents act by disrupting cell membranes. Disrupting of a membrane is caused by the mechanism of protein theft denaturation. Detergents should be used at a concentration appropriate for the formation of micelles, and this micelle starts endothelial damage. Damage of a vein occurs within minutes of the administration of these agents. Typically detergent sclerosants include polidocanol, sodium tetradecyl sulfate, sodium morrhuate, and ethanolamine oleate used mainly for endoscopic control of bleeding.

Irritant/corrosive agents act by a different mechanism and vary greatly in chemical nature and properties, and some are quite dangerous.

These agents are ethanol and phenol, polyiodinated iodine (which can cause full-thickness vessel destruction in seconds), chromated glycerine, and glycerine/lidocaine/.

Liquid sclerotherapy is usually applied to telangiectasias, spider veins, and small varicosities that persist after vein stripping. Complications, including allergic reactions, thrombophlebitis, and skin necrosis or hyperpigmentation, are rare. When a vessel is treated sequentially from bigger to smaller, from deeper to superficial, over 90% of vessel can be treated. Sclerotherapy can be realized as an additional procedure to previous surgical or endovenous therapy, or as a separate therapy for smaller vessel liquid sclerotherapy and for bigger vessels as foam sclerotherapy.

Foam sclerotherapy is the application of foam into the vessels. Under US guidance, also known as ultrasound-guided sclerotherapy, is a technique for eliminating varicose veins, particularly larger ones. It's performed by injecting the veins with a foam that causes the veins

to scar inside, so that they eventually harden, close up, and disappear. Foam sclerotherapy mixes a chemical (EU – aethoxysklerol) and a gas (air), yielding a thicker, creamy consistency. The foam sclerosant drug is more efficacious than the liquid one in causing sclerosis, for it does not mix with the blood in the vessel and in fact displaces it, thus avoiding dilution of the sclerosant to cause maximal sclerosant action and is useful for longer and larger veins. The foam is produced manually, actually the most popular method is Tessary method (Figure 5). Foam is produced by two syringes, filled by liquid of different concentration, connected by medical three-way tap and then, moved the plungers of both syringes back and forth for 20 times to produce sclerosing foam. With higher concentrated foam (3%) is possible occlude even GSV and SSV, but recurrence of reflux is higher in relation to endovenous ablative methods.

Figure 5. Foam sclerotherapy of atypically localized trans fascial insufficient perforating vein.

Saphenous Sparing Operations – ASVAL, CHIVA

Traditional surgery gives a radical solution in the treatment of CVI and varicose veins by phlebectomy of varicose collateral veins and high ligation and stripping of the saphenous vein. The theory is based on the principle that the varicose veins spread from top to bottom, and then a smaller collateral veins of the leg, which are the real varicose veins, superficial and therefore visible [72].

However, it does not explain the numerous cases of varicose veins with saphenous veins not affected by the disease.

ASVAL – ambulatory selective vein ablation under local anesthesia involves ambulatory phlebectomy of all varicose tributaries, with preservation of the great saphenous vein and small saphenous vein, irrespective of their competence. The saphenous vein is preserved. Even if GSV is affected by the varicose disease, simply because of removing the dilated collateral veins. By this step is possible to fully recover its function. The ASVAL method is based on the ascending theory of varicose vein evolution, on the premise that reflux usually ascends from the tributaries toward the saphenous trunk. The main argument in favor of preserving the great saphenous vein is the essential physiologic role that the saphenous vein

could play in superficial drainage and, to a lesser extent, its availability as revascularization material. ASVAL approach may be performed using endovenous techniques. There are good technical success rates and clinical results disease in patients with segmental GSV reflux and a competent terminal valve.

CHIVA- conservative ambulatory hemodynamic management of varicose veins is a method to decrease the superficial venous pressure. The goal of CHIVA is to decrease the hydrostatic pressure by ligations placed in specific areas in the superficial venous system and to maintain the drainage function of the superficial veins, usually via a reversed flow. The CHIVA method is performed in an outpatient setting and under local anesthetic.

When varicose veins form in the venous system, the blood flows in the wrong direction in some places. Affected regions are tied off (ligated) according to a predetermined plan to restore correct blood flow through the remaining veins.

Surgery of a Deep Venous System

Deep venous reflux in the lower limbs is defined as reflux affecting the deep venous system. The reflux can be segmental or axial. Axial reflux means uninterrupted reflux from the groin to calf and segmental is limited reflux to a segment (e.g., femoral, popliteal...). Deep venous reflux mostly arises from three aetiologies: secondary - CEAP classification: Es (post-thrombotic syndrome), primary- CEAP classification: Ep (primary deep valve incompetence) and congenital – CEAP classification: Ec (congenital valve malformation).

Es (see above CEAP classification) is the most common etiology (60–85% of cases), and valve lesion is a consequence of thrombosis or inflammation of the vein wall, followed by a recanalization. Valve has been completely or partially damaged and retracted and adherent to the vein wall. Ascending and descending phlebography is crucial examination method before the operation.

Correction of a Deep Venous System

Valvuloplasty aims are to restore the competence of the valve by correcting the anatomical defect.

Operations in Valvular Insufficiency of a Deep Venous System

Internal Valvuloplasty

First proposed by Kistner, variations in the technique have been proposed by Raju, Sottirai, and Tripathi to improve the valve exposure and to perform the surgical correction. The main goal is reducing the risk of tearing the free edges during the phlebotomy. This technique involves venotomy and correction of the valve leaflet defects under direct visualization.

External Valvuloplasty

Valvuloplasty is performable without phlebotomy by narrowing the lumen with some stitches at the cusp insertion angle: Transmural valvuloplasty. Transcommisural valvuloplasty

has the same purpose but unlike the former requires stitching of the cusp insertion. External valvuloplasty can be made with or without endoscopic supervision.

External Valve Banding

The principle of external valve banding is to reduce the caliber of the vein without opening of a vein to restore valve competence. Different materials for banding the vein have been used: Dacron cuff, Venocuff, Venocuff, polytetrafluoroethylene (PTFE) and bovine pericardium.

Vein Transplant

Vein transplant principle consists in inserting a segment of a competent valvulated vein. The best and most usable are brachial and axillary veins. The brachial vein transplant was described by Taheri and the axillary vein transplant by Raju. This segment is implanted in the incompetent deep venous network. The best-matched size for femoral level is the axillary vein; form popliteal vein is the best option the brachial vein.

Neovalve

The principle is to construct an autologous valve by using the patient's venous tissue. The neovalve can be created with the GSV termination, opportunely sectioned, shaped and invaginated into the femoral vein to function as a valve or by dissecting the vein wall to obtain a flap, which will work as a valve after adequate fixation [85]. The technique for constructing a neovalve is not always the same and it depends on the anatomical condition of the wall.

Operations for Obstruction of the Deep Venous System

Unilateral occlusions of the pelvic veins may be corrected by a Palma operation. In the classic Palma operation, the contralateral long saphenous vein is suprapubically led to the opposite side and is anastomosed end-to-end or end-to-side with the common femoral vein of the occluded side for venous drainage. Also spirally wall reinforced PTFE grafts showed favorable results.

Circumscribed occlusions of the superficial femoral vein can be interposed by the May-Husni operation. Thereby the ipsilateral long saphenous vein is implanted end-to-side into the popliteal vein. This second operation is recommended to perform under the protection of a temporary av-fistula, which increase flowthrough venous bypass and decrease the probability of bypass thrombosis. The May-Husni procedure is rarely used because of the small number of patients with post-thrombotic segmental femoral vein obstruction alone.

Deep Vein Thrombosis

- Pain in the thigh or calf sometimes accompanied by edema. Half of the patients are asymptomatic
- History of recent surgery, trauma, cancer, prolonged immobilization, or oral contraceptive use
- The clinical impression is accurate in 50% of cases
- Venous duplex ultrasound is the diagnostic modality of choice

The Virchow is the cornerstone for assessment of risk factors for DVT.

The cause, in most cases, is multifactorial. The diagnosis of DVT cannot be made solely based on presenting symptoms and signs; up to half of the patients with acute thromboses have no abnormality detectable in the involved extremity. Duplex ultrasound has now become the test of choice. It is a noninvasive examination, with specificity and sensitivity of greater than 95%. Magnetic resonance venography shows promise as a new diagnostic study for this disorder. Measurement of D-dimer levels is too nonspecific.

Treatment

Treatment is concentrated to reduce the incidence of complications associated with DVT. Short-term complications include recurrent DVT or pulmonary thromboembolism, while long-term complications include the development of varicose veins and chronic venous insufficiency. The primary treatment of DVT is systemic anticoagulation. Warfarin is administered after therapeutic heparinization. LMWH in the treatment of DVT is safe and effective as standard unfractionated heparin in the treatment of DVT.

Superficial Vein Thrombosis

- Erythema, induration, and tenderness along the superficial vein
- Usually spontaneous but can follow venous cannulation

Superficial thrombophlebitis may appear spontaneously in patients with varicose veins, in pregnant or postpartum women, or patients with thromboangiitis obliterans or Behcet disease. The patient presents complaining of localized extremity pain and redness. Areas of induration, erythema, and tenderness correspond to dilated and often thrombosed superficial veins. Superficial thrombophlebitis must be distinguished from other entities as ascending lymphangitis, cellulitis, erythema nodosum, erythema induratum, and panniculitis.

Treatment

The treatment of superficial thrombophlebitis starts with the administration of nonsteroidal anti-inflammatory drugs, local heat, elevation, and support stockings or elastic wraps. Septic thrombophlebitis requires treatment with broad-spectrum intravenous antibiotics. Chronic venous insufficiency can result from congenital venous valvular insufficiency or can result from previous venous thrombosis.

Chapter 292

COMPLICATIONS AND RECOVERY IN VASCULAR SURGERY

Peter Berek*, MD, PhD

Department of Vascular Surgery, East Slovak Institute of Cardiovascular Diseases,
Pavol Jozef Safarik University, Kosice, Slovakia

ABSTRACT

The problem of postoperative complications in vascular surgery continues to be relevant. The development of postoperative complications is influenced by many factors, mainly the polymorbidity of patients, eyelids, and the multiplicity of atherosclerosis. It is accepted to allocate the general and local, early and late postoperative complications. General complications include syndrome of acute circulatory failure, cardiac decompensation, respiratory decompensation, renal decompensation, neurologic decompensation, hemocoagulative decompensation, mental decompensation. Of the local complications, the main place is occupied by bleeding and infection. Causes of early and late postoperative hemodynamic complications (thrombosis, false aneurysm of the anastomoses) are divided into major and concomitant. The main reasons include surgical errors (technical errors in the implementation of the anastomoses, excess or tension of the shunt, its torsion) and the failure of the distal bed. To the accompanying - violations of the blood coagulation system and general hemodynamic disorders. For the prevention of postoperative complications plays an important role preoperative preparation, risk stratification, and optimal drug therapy are necessary, intraoperative and postoperative prevention of infection. During surgery, it is important to choose an optimal and adequate volume of surgery considering the patient's age and polymorbidity. In the postoperative period, intensive postoperative monitoring and early rehabilitation of the patient are of great importance.

Keywords: vascular postoperative complications, bleeding, false aneurysm, infection, thrombosis, ischemia, compartment syndrome, amputation

ABBREVIATIONS

AAA –	abdominal aortic aneurysm
ARDS –	acute respiratory distress syndrome
ARF –	acute respiratory failure
CRP –	C-reactive protein
CTA –	computed tomography angiography
MODS –	multiple organ dysfunction syndrome
PDGF –	platelet-derived growth factor
PET –	positron emission tomography
PMI –	perioperative myocardial infarction
SIRS –	systemic inflammatory response syndrome
TIA –	transient ischemic attack
Tcp02 –	transcutaneous oxygen tension

INTRODUCTION

The number of vascular bed surgeries increases with the increase in the prevalence of vascular diseases and the epidemic of diabetes mellitus. Most patients with peripheral arterial diseases are polymorbid being at high risk of developing postoperative complications [1, 2]. Also, postoperative complications may result from diagnostic or technical errors, namely inadequate or incomplete interpretation of the objective methods of examination (angiography, computed tomography angiography (CTA)) and surgical errors (inadequate assessment of intraoperative findings, technical errors, etc.) [3]. In vascular surgery, there are general and local complications. In terms of the period of occurrence, they are divided into early and late complications [4, 5].

GENERAL COMPLICATIONS

The development of general complications is affected by patients' polymorbidity. According to statistics, among vascular patients, coronary lesions and cerebral atherosclerosis are diagnosed in 40-60% of the cases, atherosclerosis of the renal arteries is found in 23-42% of the cases, diabetes mellitus and its complications are detected in 15-20% of the patients [2]. General complications include syndrome of acute circulatory failure, cardiac decompensation, respiratory decompensation, renal decompensation, neurologic decompensation, hemocoagulative decompensation, mental decompensation (Table 1).

Syndrome of acute circulatory failure is the leading cause of complications and mortality among the patients who underwent cardiac or vascular surgery. The most serious manifestation of acute circulatory failure is a circulatory shock, which is a clinical syndrome characterized by inadequate tissue oxygenation leading to decreased oxygen intake, anaerobic metabolism and lactic acidosis [6, 7].

Table 1. General complications

Syndrome of acute circulatory failure	
Decompensation	Cardiac
	Respiratory
	Renal
	Neurologic
	Hemocoagulative
	Mental
Multiple organ dysfunction syndrome	

Depending on the etiological factor in the operated patients, there are the following types of shock:

Cardiogenic shock (acute heart failure):

- initially low myocardial functional reserves;
- perioperative myocardial infarction;
- myocardial contractile dysfunction;
- cardiac rhythm disturbances and cardiac conduction defect;
- pericardial tamponade.

Hypovolemic shock (a decrease in total blood volume):

- bleeding;
- dehydration.

Distributive shock (excessive vasodilation):

- anaphylactic shock;
- septic shock;
- neurogenic shock.

Obstructive shock (physical obstruction of the great vessels):

- pulmonary embolism;
- superior vena cava syndrome.

Traditionally, clinical signs of shock are impaired consciousness, low temperature of the extremities, pale and mottled skin, a weak rapid pulse, low blood pressure and a decrease in urine output (oliguria/anuria) [8].

In addition to severe hemodynamic abnormalities, the severity of acute circulatory failure depends on several factors which may lead to the inadequate supply of organs and tissues with oxygen on the background of relatively normal central hemodynamics:

- low oxygen-carrying capacity of the blood (anemia and/or arterial hypoxemia);
- humoral imbalance;
- electrolyte imbalance;
- peripheral arteriovenous shunting;
- increased blood flow rate on the background of a decrease in the metabolic rate;
- capillary stasis due to inadequate perfusion and disseminated intravascular coagulation (DIC) syndrome;
- increased metabolic activity in the absence of cardiac efficiency reserves;
- impaired oxygen diffusion through the capillary wall due to increasing tissue swelling.

In the early postoperative period, the metabolic rate increases due to surgical aggression, activation of the sympathoadrenal system, high body temperature, energy expenditure for rewarming due to parenteral administration of cold solutions. Thus, the increase in cardiac output after surgery is considered as an adequate response of the circulatory system to surgical trauma [9].

Cardiac complications can manifest themselves as angina pectoris, heart failure, arrhythmia, myocardial infarction, death [10]. Acute myocardial infarction observed during surgery or in the early postoperative period is a complication of surgical treatment and is known as perioperative myocardial infarction (PMI). Most patients develop myocardial infarction during surgery or within the first postoperative day [11]. Pathogenetically important risk factors for developing PMI are the poor state of the distal bed of the coronary arteries, preoperative unstable angina, lesions of the left main coronary artery [12].

The diagnosis of PMI is based on the analysis of the clinical picture, electrocardiography data, the study of serum enzymes and echocardiography [13]. The generally accepted clinical criteria for myocardial infarction have no informative value during and after surgery. The first signs of myocardial infarction in such patients are, as a rule, acute circulatory failure, persistent rhythm disturbances, sudden circulatory arrest. The gold standard of ECG diagnostics of macro-focal PMI is the presence of a new Q wave in one or more leads with a duration of not less than 0.04 sec which is seen on the ECG within 28-48 hours if there are no conduction abnormalities [11, 14].

Treatment of Complications

- maintenance of adequate circulation and respiration;
- prevention and treatment of life-threatening arrhythmias;
- attempts to restore coronary blood flow at the site of occlusion (angioplasty, coronary artery stenting; emergency surgery - coronary artery bypass graft surgery) which should be performed not later than 6 hours after the development of PMI;
- measures aimed at limiting the infarct zone (intra-aortic balloon pump counterpulsation, beta blockers, calcium antagonists, preparations affecting metabolism);
- anticoagulant and antiplatelet therapy;
- prevention and treatment of comorbid complications.

The mortality rate in PMI ranges between 20 and 24%; however, if PMI co-exists with cardiogenic shock, the mortality rate reaches 60-90%. Therefore, the selection of the patients and pharmacological optimization of cardiovascular risk factors before surgery are extremely important [11, 15].

Respiratory Complications

Acute respiratory failure, atelectasis, bronchospasm, analgesic-induced hypoventilation or hypoventilation resulting from residual neuromuscular blockade, infection, pulmonary edema, acute respiratory distress syndrome (ARDS), pulmonary failure [16].

Acute Respiratory Failure

There are two types of acute respiratory failure (ARF) – hypoxemic and hypercapnic. ARF may result from the disorders at the following levels:

- central neural respiratory control;
- regulation at the level of the peripheral nervous system and neuromuscular transmission;
- the capability of the respiratory muscles and chest framework;
- air way patency.

In the early postoperative period, ARF may occur as a result of the combination of the factors above [17]. When arterial hypoxemia develops, the following compensatory factors are involved: hyperventilation, pulmonary blood flow redistribution due to increased pulmonary artery pressure, increased cardiac efficiency, elevated hemoglobin levels due to reserves stored in the body depot. In acute cases, the efficiency of compensatory mechanisms is limited; as a result, organ and tissue hypoxia may develop [7].

Table 2. Etiological factors involved in the development of acute renal failure

Prerenal	Parenchymal	Postrenal
Decreased cardiac output, cardiogenic shock	Nephrotoxic factors Radiological contrast media	Ureteral obstruction
Pronounced hemolysis during the transfusion of incompatible blood	Myoglobinuria	A blood clot in the urinary bladder
Septic shock	Acute tubular necrosis	Urethral obstruction
Hypovolemia	Renal artery embolism and thrombosis	

Renal Complications

Acute renal failure. Prerenal failure is caused by hypovolemia or dysfunction due to decreased cardiac output. Renal parenchymal failure results from acute tubular necrosis. Postrenal failure is less common and is caused by ureteral or urethral obstruction [18]. To prevent renal failure, it is important to provide renal protection during vascular surgeries, especially in patients with the predictors of chronic renal failure [19].

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome (MODS), also known as multiple organ failure (MOF), is one of the most serious complications occurring in the postoperative period. The trigger mechanism of the development of multiple organ failure of any genesis is systemic inflammatory response syndrome (SIRS). The process of its formation is non-specific and does not depend on the etiology of the critical condition [20, 21].

Preoperative risk factors for the development of MODS include:

- the patient's a critical condition;
- patient's age over 60 years;
- cardiovascular failure;
- diabetes mellitus;
- renal failure;
- respiratory failure with obstructive disorders and a decrease in pulmonary function and oxygenation.

MODS may develop due to the occurrence of the following complications during surgery and in the early postoperative period:

- massive blood loss and hemotransfusion;
- the shock of various etiology;
- anaphylactic reactions;
- acute lung injury and respiratory distress syndrome;
- prolonged artificial blood circulation

In the late postoperative period, a person develops sepsis which results from a systemic response to microbial invasion.

- Neurological complications: acute cerebrovascular disease and transient ischemic attack (TIA).
- Coagulation complications: hypercoagulable and hypercoagulable states, the inefficiency of anticoagulant therapy.
- Mental decompensation: The development of postoperative delirium in 38.9% of the patients who underwent vascular surgeries. In this group of the patients, severe postoperative complications were more common (38.1% versus 18.2%) [22, 23].

LOCAL COMPLICATIONS

Local complications develop in the surgical field and are local. Considering the specificity of arterial reconstructions, local complications are often dramatic [5]. In terms of the period of occurrence, they are divided into early complications which develop within the first postoperative hours and days and late complications which occur several months or years after surgery [23, 24].

Table 3. Vascular Complications

<i>Local vascular complications</i>
Reconstruction thrombosis
Thromboembolic complications
Reconstruction infection
Bleeding
Anastomotic pseudoaneurysm
Deep vein thrombosis
<i>Local nonvascular complications</i>
Lymphatic fistulae (most often in the subinguinal region)
Postoperative extremity swelling
Compartment syndrome
Local peripheral nerve injury and ischemic neuropathy
Operative wound infection
Sexual dysfunction
Ureteral obstruction. Intraoperative injury during aortic reconstruction
<i>Remote vascular complications</i>
Visceral ischemia (more often colon ischemia)
Spinal cord ischemia
Atherothrombotic complications -peripheral microemboli

EARLY VASCULAR COMPLICATIONS

Early vascular complications include those occurring directly in the postoperative period and during hospitalization. They include bleeding, early reconstruction occlusion, early infection, lymphorrhea, nerve, and spinal cord injuries [25, 26].

Bleeding

Bleeding occurs most often within the first postoperative hours. It is caused by a technical error or hypocoagulable state which is associated with heparinization or antiaggregant therapy [27, 28].

There are the following types of bleeding:

- a) bleeding from the anastomosis site or suture line due to suture abrasion or too wide suture spacings. At the site of suture abrasion, moderate bleeding occurs. This type of

bleeding is stopped by compression of the anastomosis site and heparin neutralization. Bleeding may be caused by injury from arterial clamps (in case of pronounced atherosclerotic changes) or traction sutures used in the dissection of blood vessels as well.

- b) bleeding from a surgical wound due to the slipping off of the ligature from the vessel, inadequate coagulation of small blood vessels. Vascular injury may occur while suturing the surgical wound (injury with a needle). In this case, bleeding is usually stopped by tightening the suture.
- c) bleeding from the great saphenous vein when it is used as a conduit for a bypass. In this case, bleeding may be caused by the slipping off of the ligature or clip from the dissected collateral branch. This type of bleeding occurs most commonly in poor blood outflow that increases the pressure exerted on the wall of the great saphenous vein.

Blood Loss Criteria

If surgical bleeding is accompanied by secondary disorders of hemostasis, within the first hours, if there are signs of bleeding, conservative hemostatic therapy is performed – the normalization of coagulation parameters – plasma, erythrocyte concentrate, hemostatic therapy. If heparin is active, it is neutralized with protamine sulfate. It is often a very difficult task to differentiate between the surgical cause of bleeding and hemostatic disorders. In such cases, it is very important to prevent massive blood loss. Massive blood loss and hemotransfusion result in DIC syndrome, SIRS and MODS [10]. If bleeding continues after conservative measures, emergency surgery is performed.

Tactics of treating bleeding patients depend on their clinical condition and the volume of wound secretion in the Redon drain canisters. If in the early postoperative period, the volume of blood secreted is 200-300 ml or there is an active blood secretion to the Redon drain canisters within several hours after two transfusions and hemostatic therapy, it is indicated to perform re-surgery to stop bleeding. On general examination, the patient presents with pallor, low blood pressure and hemoglobin levels. At the site of the surgical wound, resistance phenomena associated with hematoma progression may be observed. After carotid endarterectomy, in addition to the resistance on the neck, bleeding patients may develop signs associated with compression by hematoma which manifest themselves as a tracheal deviation, breathing and swallowing difficulties and sometimes there is the need for intubation [28].

During abdominal or retroperitoneal surgery, a hematoma may be not visualized when examining the patient. The lack of the secretion to the drain or minimal secretion does not mean that there are no signs of bleeding since the Redon drainage system may be impassable due to the presence of the blood clots. Diagnostic criteria include the patient's clinical condition, hemoglobin concentration and the objective methods of examination. The latter involves an ultrasound scan, CT (Figure 1).

Blood loss is considered to be significant if within 2-4 hours in the absence of pronounced coagulation disorders or the presence of hypercoagulation signs, there is the loss of 70 ml/m² of hemorrhagic fluid with the hematocrit close in value to blood hematocrit through the drain. This is the indication for re-surgery to achieve hemostasis.

Figure 1. CT angiography of retroperitoneal hematoma.

During emergency surgery, the revision of the surgical wound is performed. During vascular surgery, the revision of arterial reconstruction zone is required. If the blood leaks out at the anastomosis site, the hemostatic suture is applied. If the suture is abraded, the method of choice is the mattress suture which reduces the possibility of suture abrasion. If there is bleeding from the collateral vessels, the ligature is placed, or the sutures are applied over the bleeding site. If there is bleeding from small collateral vessels, coagulation is used. In the case of diffuse bleeding, in addition to coagulation, local hemostatic agents can be used.

Reconstruction Occlusion

There is early and late occlusion of the reconstruction. Early occlusion is that occurring within 30 days after surgery. Late occlusion is that occurring 30 days after primary surgery [29].

Early occlusion is observed in approximately 5% of the cases; in 25% of these cases, it is caused by a technical error during surgery [30].

There are the following causes of early occlusion:

- a) incorrect indication for surgery:
 - the bypass is performed in case of: a) weak blood inflow; b) poor blood outflow (peripheral injury).

- use of prosthetic material in patients with weak blood inflow and peripheral injury that increases the risk of thrombosis.
- b) incorrect surgical technique:
- error in the proximal anastomosis;
 - rotation or refraction of the prosthesis or the vein;
 - error in the distal anastomosis.

In lower extremity arterial reconstructions, bypass occlusion manifests itself as ischemia, namely lower extremity pain, the absence of pulse below the distal anastomosis, cold extremity, sensory and motor deficit [5, 30].

The diagnosis is clarified by an ultrasound scan or angiography in addition to the clinical picture [31].

In carotid artery reconstructions, acute occlusion manifests itself as acute cerebrovascular disease. CTA is the best method of carotid artery occlusion verification.

In visceral artery reconstructions, acute occlusion manifests itself as visceral ischemia; however, the clinical course is not so dramatic as that in acute carotid artery occlusion or lower extremity bypass occlusion.

A. mesenteric superior or inferior occlusion may manifest itself as gastric ischemia with the progression to gangrene, perforation, and peritonitis [32].

Visceral reconstruction occlusion is verified by CTA. Renal artery reconstruction occlusion may manifest itself as oliguria or anuria.

Indications for Surgical Revision in Acute Occlusion after Arterial Reconstruction

Lower Extremity Bypass Occlusion

Bypass thrombectomy with a Fogarty catheter is performed in the region of the distal anastomosis; it is necessary to pass through the proximal anastomosis and restore blood flow to the bypass. Then, the revision of the distal vascular bed through the distal anastomosis is performed. If in the region of the distal anastomosis, it is difficult to pass through the proximal anastomosis, it is better to open the wound in the region of the proximal anastomosis and to perform the revision of the blood flow and the anastomosis itself through small access in the proximal anastomosis region.

One of the most common problems is intima dissection which creates favorable conditions for occlusion. In such a case, it is better to disconnect the anastomosis, to perform intima fixation and to create the anastomosis again [33].

In case of prosthesis rotation, it is necessary to disconnect the distal anastomosis, to align the graft along the axis and to create the distal anastomosis again.

If there is no technical error, occlusion may be caused by incomplete removal of the blood clots when restoring the circulation, air embolism or an insufficient dose of heparin during the primary reconstruction. In this case, the only thrombectomy is performed. If bypass occlusion occurs several times, it is necessary to exclude the hypercoagulable state.

Infection

In vascular surgery, infection is an important problem [34]. It is necessary to differentiate between wound infection occurring in approximately 5% of the cases and prosthetic infection that develops in 0.2-1% of the cases [35]. The risk of developing infection is higher in urgent patients as compared to those undergoing elective surgeries [36]. Infections are classified according to the Szilagyi classification [37].

- I. Phlegmon of the surgical wound
- II. Infection of the subcutaneous tissue
- III. Infection of the vascular prosthesis

The patients with infection Grade, I and II according to the Szilagyi classification, are at higher risk of developing prosthetic infection [38].

Infections are classified as early, if they occur within three months after surgery, or late, if they occur three months after surgery [39].

The prosthesis may be infected in the following ways:

- a) intraoperative contamination through the surgical wound;
- b) spread of infection by bacteremia;
- c) mechanical erosion into the gastrointestinal or genitourinary tracts;
- d) spread of infection per continuities.

Risk factors for the development of infection [40]:

- a) poor adherence to the principles of intraoperative aseptic techniques;
- b) emergency surgery;
- c) hematoma or seroma in the postoperative period;
- d) long-term surgery or hospitalization;
- e) postoperative wound infection.

Re-surgery is an additional risk factor for remote prosthetic infection. In addition to local risk factors, general risk factors such as diabetes mellitus, chronic renal failure, immunosuppression, hormonal therapy increase the risk of infection as well [41].

The most common causative pathogen of prosthetic infection is *Staphylococcus aureus* [42]. Over recent years, in patients with aortoenteric fistulae, infections caused by *Staphylococcus epidermidis* or gram-negative bacteria have been observed more often [43]. Mycotic infections are rare, but if they are present, they occur due to *Candida albicans* and are typical for the immunocompromised patients.

Treatment of infection in vascular surgery is problematic and is often followed by limb loss [44, 45]. Clinical manifestations of prosthetic infection occur over time. Infection in the early postoperative period is caused by wound contamination due to the reconstruction in a potentially infected field, for example in trauma. Wound contamination may be caused by contact with the gastrojejunal tract when placing the aortobifemoral prosthesis [40, 46].

The inguinal wounds are associated with the highest risk of wound infection due to their proximity to the anogenital region. Infections caused by *Staphylococcus epidermidis* or gram-negative bacteria are more virulent. Clinical signs of inflammation include swelling, redness,

pain, fever. If the prosthesis is infected, bleeding or prosthetic occlusion may occur at the anastomosis site [47]. Bleeding may be massive and fatal. Infections caused by *Staphylococcus epidermidis* are less virulent. Most commonly, they manifest themselves several months or even years after surgery [38].

Typical clinical manifestation is anastomotic pseudoaneurysm or fluid collection around the prosthesis (Figure 2).

Figure 2. CT angiography - Perigraft fluid collection.

Systemic signs of infection are rare. The diagnosis is made based on clinical manifestations. The cultivation of the wound and fluid accumulated around the prosthesis is of great importance. The blood test indicates leukocytosis, elevated pro-inflammatory parameters (C-reactive protein (CRP), procalcitonin). Positive blood culture is observed in 5% of the cases only [43].

An ultrasound scan may detect hematoma, seroma or abscess in the subcutaneous tissue or around the prosthesis [48]. If CT 3 months after surgery illustrates the presence of fluid and air around the prosthesis, it indicates prosthetic infection (Figure 3). CTA may show pseudoaneurysm which is also typical for prosthetic infection.

Figure 3. CT angiography - air around the prosthesis.

Figure 4. PET-CT infected prosthesis of aortobifemoral graft.

The next objective method of diagnosing prosthetic infection is leukocyte scintigraphy. The accuracy of this examination in detecting infection is 80-90%. Over recent years, positron emission tomography (PET) scan or PET in combination with CT (PET-CT) have been used for diagnosing prosthetic infection more frequently (Figure 4).

If aortoduodenal fistula is suspected, endoscopic examination of the distal portion of the duodenum is recommended [49].

Treatment

If the infection is localized in the subcutaneous tissue above the bypass, this means that infection Grade I and II according to the Szilagyi classification is present [37]. Treatment includes wound revision and debridement. The wound should be left open for daily dressings. In addition to necrotomy, antibiotic therapy based on the results of antibiotic susceptibility testing should be prescribed [50]. If the infection spreads to deeper layers, there is a need to open all the infected areas and perform necrotomy. The bypass can be preserved in patients with less virulent infection, and those with the signs of infection occurred up to 3 months after primary surgery, or if the infectious process spreads only to the part of the bypass [42]. Treatment of venous bypass infection may be successful for the preservation. The principle of treating infection is standard, namely intravenous antibiotic therapy, local necrotomy and vacuum therapy [50]. Even though some publications reported the efficacy of conservative treatment in 84% of the cases, in general, prosthetic infection was successfully cured using conservative treatment in 15% of the bypasses only [38]. In other cases, the entire bypass or its infected part needed to be removed. If primary surgery was performed in the patient with intermediate claudication, it is possible not to create a new bypass but to perform venous plasty in the areas where anastomoses were created. However, in most cases, there is a need for limb revascularization. The possibilities of revascularization are as follows [51]:

- a. extra-anatomic bypass;
- b. in situ bypass.

The extra-anatomic bypass is a traditional method of choice for treating the prosthetic infection which includes the removal of the prosthesis, necrotomy of the infected area and extra-anatomic reconstruction [45, 52]. In the aortoiliac region, extra-anatomic reconstruction means as follows: the removal of the aortobifemoral bypass, suturing of the distal aorta (blind suture) and lower extremity revascularization using the axillofemoral bypass (Figure 5).

Figure 5. CT angiography of the axillofemoral bypass.

In case of only one aortobifemoral bypass graft infection, it is possible to extract the infected graft of the aortobifemoral bypass with further reconstruction using the prosthetic material, bypassing the infection in the inguinal wounds via foramen obturatum [46, 51]. On the medial side of the thigh, the distal anastomosis is placed on the superficial femoral artery. In extra-anatomic reconstructions, limb loss up to one year ranges between 10 and 25%; the perioperative mortality rate is 15-22%; 60-80% of the patients live more than one year. Axillofemoral bypass infection occurs in 3-25% of the cases [52].

The results above of extra-anatomic reconstructions have led to the search for new opportunities to perform in situ anatomic reconstructions [53, 54]. The patients with less virulent infection are more suitable for in situ arterial reconstructions. In such a case, to replace an infected prosthesis, there are the following options [55, 56]:

- a) the great saphenous vein;
- b) the femoral vein;
- c) antibiotic-loaded prosthesis;
- d) cryopreserved arterial allograft.

The great saphenous vein has a smaller diameter; therefore, it cannot be used for the aortoiliac region. However, it is the method of choice for the femorofemoral crossover bypass or the reconstruction in case of infection in the inguinal area [54].

In the 90's of the last century, some research works where the femoral vein was used for in situ reconstructions appeared [46]. The superficial femoral vein was dissected on the thigh immediately below the bifurcation of the common femoral vein (Figure 6).

Figure 6. Vein interpositum from common femoral artery to deep femoral artery (Superficial femoral vein).

After such a procedure, approximately 15% of the patients developed deep vein insufficiency. It is possible to perform in situ reconstructions of the aortobifemoral prosthesis using two femoral veins [51]. After such procedure, Clagett noted perioperative mortality in 10% of the cases, bypass patency six years after surgery in 80% of cases and extremity preservation six years after surgery in 90% of cases. Fifty-two percent of the patients lived more than five years [54].

The next possibility is in situ reconstruction using a cryopreserved arterial allograft from the donor aortoiliac region (Figure 7).

Figure 7. Aortal allograft (intraoperation photography).

The results were similar to those when performing reconstruction using the femoral vein. The disadvantage was a higher possibility of aneurysmal graft expansion, stenosis and the risk of degeneration which occurred in 5-20% of the cases [53]. In some case, the antibiotic-loaded prosthesis can be used for in situ reconstructions. The most frequently used antibiotic is rifampicin. This type of surgery is indicated for patients with slightly virulent infection without general inflammatory signs. The antibiotic-loaded prosthesis can replace only one

part of the aortobifemoral bypass prosthesis [56]. If this in situ reconstruction is performed in the abdominal cavity, the prosthesis should be covered by the omentum. In surgery in the groin, the prosthesis should be covered by the muscle. After surgery, the patients should undergo intravenous antibiotic therapy for six weeks. After using an antibiotic-loaded prosthesis, reinfection is observed in 5-10% of the cases. A 2-6-week course of intravenous antibiotic therapy is required after both extra-anatomic reconstruction and in situ replacement of the prosthesis [53].

Considering the fact that infection is one of the most serious complications in vascular surgery with a high percentage of limb loss and mortality, its prevention is of great importance [57]. The requirement for the prevention of prosthetic infection includes strict adherence to the principles of aseptic and antiseptic techniques and the limitation of direct contact of the prosthesis with the skin [58]. An important stage is maintaining hemostasis during surgery and adequate drainage of potential hematomas or seromas [44]. To prevent prosthetic infection, it is important to avoid single-stage interventions in the gastrointestinal or genitourinary tracts with arterial reconstruction. Also, antibiotic prophylaxis is required [59].

Lymphatic Secretion

The main arteries are located along lymphatic vessels. During dissection, lymphatic collectors may be damaged. Each arterial reconstruction has the risk of lymphatic secretion in the postoperative period [60]. Anastomotic drainage removes lymphatic secretion, if it is present. A non-drained seroma may serve as the risk factor for infection development.

In most cases, lymphatic secretion stops after several days. If the signs of lymphorrhea persist over a week, surgical revision is required. Methylene blue is applied distally to the dorsal surface of the operated extremity, and after several minutes, the affected lymphatic collector who needs to be sutured is visualized in the groin [61]. Complications such as chylous ascites or chylothorax are less common [62].

Nerve and Spinal Cord Injuries

Nerve injuries after arterial reconstructions are rare. They can be caused by direct nerve damage during surgery, ischemic nerve damage or insufficient revascularization in spinal cord injury [63, 64]. Among arterial reconstructions, nerve injury occurs most often during carotid endarterectomy accounting for 5-7% of the cases. Most commonly, n. hypoglossus, n. facialis, and n. laryngeus recurrens are damaged [65].

In most cases, these iatrogenic injuries are transitory in nature. Damage to the femoral nerve and the upper extremity nerves is rare. During venous surgery, when stripping the great saphenous vein, n. safenus is most often injured accounting for 27-35% of the cases [66].

The prevention of nerve injuries is a careful dissection of the anatomical structures with the knowledge of topographical anatomy and functioning of the nerves. The prevention of n. safenus injury also involves limited stripping during which only the great saphenous vein above the knee is removed [66].

Spinal cord ischemic injury occurs during surgical repair of the thoracic aorta and accounts for 2-10% of the cases. During aortoiliac reconstructions, the risk of spinal cord ischemia is 0.25% [66]. The artery which most frequently branches off from one of the paired intercostal arteries at the level of Th8-Th12 is important for the spinal cord blood supply. At

the same time, the origin of the artery of Adamkiewicz is variable, and it can branch off from the lumbar arteries. The internal pelvic arteries are also involved in the spinal cord blood supply. Paraplegia can be caused by the circulatory arrest in the lumbar arteries during aortic clamping or the removal of the internal pelvic arteries from the circulation. Due to the variability in the spinal cord blood supply, it is difficult to predict the development of its ischemia during vascular surgeries. To prevent possible spinal cord ischemia, it is recommended to preserve the circulation by maintaining flow through at least one of the internal iliac arteries [26, 65].

LATE COMPLICATIONS

Late infection is that occurring 30 days after primary surgery.

Late Occlusion of Arterial Reconstruction

Late occlusion of arterial reconstruction occurs 30 days after primary surgery [24].

Factors involved in the development of late occlusions of arterial reconstructions:

- a) bypass localization;
- b) replacement material for reconstruction;
- c) rate of disease development;
- d) long-term anticoagulant and antiplatelet therapy.

Localization

The determination of whether the bypass is passable is made during the observation period, for example for a year, three or five years [24]. Primary patency is defined as an uninterrupted patency with no bypass surgery. Secondary patency is defined as patency after bypass surgery to avoid its occlusion or after thrombolysis or thrombectomy after bypass occlusion.

Neointimal Hyperplasia

Neointimal hyperplasia is a common cause of remote bypass occlusion. Neointimal hyperplasia refers to the proliferation of all the intimal structures, especially smooth muscle cells which results in a significant increase in the volume of the extracellular fluid [67, 68]. The trigger mechanism is vascular wall injury which occurs during each reconstruction. The main role is played by platelets which release a platelet-derived growth factor (PDGF) when breaking down on the affected surface. This factor serves as a mitogen for smooth muscle cells and leads to their rapid multiplication. The process of developing neointimal hyperplasia lasts as long as several weeks due to type I and III collagen production which results from the metabolic activity of smooth muscle cells [63]. Neointimal hyperplasia is typical for distal anastomoses occurring within six months after primary surgery. An objective criterion for

neointimal hyperplasia is an anastomotic stricture. In the case of hemodynamically significant stenosis, percutaneous transluminal angioplasty is the method of choice for prevention of bypass occlusion.

In terms of the period of occurrence, vascular reconstruction occlusion has three stages.

Stage I – up to 3 months. In 25% of the cases, early occlusion is caused by a technical error during surgery [27].

Stage II – 9 months after primary reconstruction. The most common cause is neointimal hyperplasia.

Stage III – 20 months after surgery. The cause is the progression of atherosclerosis.

Diagnosis

Clinical manifestation of bypass occlusion includes limb ischemia. In a venous bypass, there is a tendency toward a gradual occlusion of the bypass which is accompanied by minimal clinical manifestations, while prosthetic bypass occlusion is accompanied by limb ischemia. The current reference standard for the diagnosis is duplex ultrasound, CTA or diagnostic angiography.

Treatment

If there are any indications for endovascular intervention or surgery, the potential success of bypass revascularization and the risk of re-surgery should be assessed [69]. If bypass occlusion is not accompanied by acute limb ischemia, conservative treatment may be used. If interventional therapy is preferable, the method of choice is thrombolytic therapy. If the results are positive, angioplasty or stenting of stenosis that resulted in bypass occlusion is performed (Figures 8-12).

Figure 8. Occlusion of femoro – popliteal prosthetic proximal bypass.

Figure 9. Thrombolytic therapy of femoro – popliteal prosthetic proximal bypass.

Figure 10. Result of successful thrombolytic therapy of femoro – popliteal prosthetic proximal bypass.

Figure 11. Stenosis of distal anastomosis of femoro – popliteal prosthetic proximal bypass.

Figure 12. Percutan transluminal angioplasty and stenting of stenosis of distal anastomosis of femoro – popliteal prosthetic proximal bypass.

The next possibility is surgical treatment. Bypass revision and thrombectomy are performed. During revision, the cause of bypass occlusion should be determined. Stenosis at the distal or proximal anastomosis is the most common [24, 70].

Three alternative methods can be used for treatment:

- plasty at the anastomosis site;
- anastomosis resection with the creation of an interposition graft;
- creation of a new bypass.

False aneurysm

Anastomotic false aneurysm occurs in 1 to 5% of the cases [42]. The most common site of a false aneurysm is the femoral artery.

The possible causes of false aneurysm are:

- disruption in the arterial wall when creating the anastomosis;
- anastomotic tension (short prosthesis);
- infection.

In most cases, a false aneurysm is caused by a technical error or infection [28]. Clinical manifestation of bypass occlusion is pulsating resistance. The objective methods of diagnosing anastomotic false aneurysm are ultrasound scan and CTA.

Figure 13. CT angiography – False aneurysm of distal anastomosis of left branch of Aortobifemoral bypass.

A false aneurysm can result in bleeding, bypass occlusion or distal embolization of a thrombus. False aneurysm is treated surgically. It is necessary to perform the revision of the affected anastomosis and to restore the reconstruction by creating an interposition graft. If there is distal anastomotic false aneurysm of the aortobifemoral bypass, the interposition graft should be inserted in the deep femoral artery. If the patency of the superficial femoral artery is preserved, the interposition graft is inserted in its proximal end. During surgery, there is a need to collect the material samples for cultivation to exclude the infection. It is more difficult to treat proximal anastomotic false aneurysm of the aortobifemoral bypass [36]. The method of choice for its treating may be the placement of the stent graft into the proximal anastomosis. These treatment tactics is recommended to be used in patients whose false aneurysm was not caused by the infection [49].

ABDOMINAL AORTA AND ILIAC ARTERIES

The 5-year patency of the aortobifemoral bypass is 90%. The patients over 60 years of age demonstrate better patency of the aortobifemoral bypass as compared to patients under 60 years of age [44]. This may be because atherosclerosis is known to be more aggressive at a young age [26]. In general, the patency of the aortobifemoral bypass is limited by the distal anastomosis; therefore, it is recommended to perform profundoplasty when performing the aortobifemoral bypass [71]. In vascular surgery, infrainguinal reconstructions are reconstructions which most frequently involve bypasses. In the infrainguinal bypass, the blood flow is lower as compared to the aortobifemoral one that may result in worse results. Another cause of poor results may be peripheral injury. The 5-year patency of the femoropopliteal bypass is presented in table 4.

Table 4. The 5-year patency of the femoropopliteal bypass

	The proximal femoropopliteal bypass	The distal femoropopliteal bypass
Venous bypass	75%	50%
Dacron bypass	45%	25%
Polytetrafluoroethylene (PTFE) bypass	35-39%	16%

Extra-anatomic reconstructions demonstrate 5-year patency in 50% of the cases only. This is because the anastomosis geometry is not perfect, the reinforced prostheses with worse elasticity are used more often; as a result, the transfer of the pulsating wave is worse.

Complications in Aortic Reconstructions

- distal embolization – emergency embolectomy is indicated;
- in an abdominal aortic aneurysm (AAA), intestinal ischemia is observed in 2% of elected surgeries and as much as 60% of emergency surgeries;
- acute pancreatitis (pain when restoring nutrition, intestinal paresis);

- d) acute acalculous cholecystitis;
- e) aortoenteric fistula (1%);
- f) ureteral injury or obstruction;
- g) sexual dysfunction.

Left-Side Colon Ischemia after Aortic Reconstructions

Left-side colon ischemia occurs in 1.5-2% of the cases and is associated with extremely high mortality rates – up to 90% [32]. The restoration or preservation of the blood flow through the inferior mesenteric artery is one of the most effective methods of preventing the development of left-side colon ischemia. In 20% of the cases, the middle colic artery is absent; in such patients, the right colic artery (the branch of the superior mesenteric artery) plays an important role in the blood supply to the left colon, especially when the inferior mesenteric artery is ligated during surgery [72]. The internal iliac arteries are responsible for retrograde collateral revascularization of the left colon directly due to anastomoses of the superior rectal artery and the branches of the inferior mesenteric artery [73]. In the patients with occlusion or subtotal stenosis of the celiac artery and the superior mesenteric artery when the blood supply to the intestine is through the inferior mesenteric artery, an additional collateral blood supply to the left colon via the internal iliac artery is of great importance. The development of acute disorders of the visceral circulation and, accordingly, intestinal ischemia after aortic reconstructions is associated with many factors [32]:

- 1) unreasonable or improper ligation of the inferior mesenteric artery;
- 2) the extent of the damage to the visceral branches and the significance of these arteries for the visceral circulation;
- 3) state and functioning of the direct intercostal anastomosis.

Depending on the severity of the visceral circulation disorders occurring after aortic reconstructions, clinical manifestations of colonic ischemia range from subclinical forms to the development of gangrene and colonic perforation with the development of severe peritonitis.

There are three stages of the pathological process:

- 1) stage of ischemia;
- 2) stage of infarction;
- 3) stage of peritonitis.

After aortic reconstructions, clinical symptoms may occur within 14 days; however, in 75% of the cases, they develop in the first 24-48 hours after surgery. The prevention of left-side colon ischemia in aortoiliac reconstructions consists of the restoration or preservation of the blood supply via the inferior mesenteric artery, if it is possible (Figure 14).

In case of the inferior mesenteric artery ligation, it should be performed as close as possible to the aorta in order not to affect the collateral relation between the left colic artery and the sigmoid arteries [74].

Figure 14. Reconstruction of inferior mesenteric artery.

In the opening of the aneurysm sac, possible embolization of the inferior mesenteric artery should be considered; therefore, it is better to apply a bulldog clamp to the inferior mesenteric artery before opening the aneurysm sac. If to restore the blood supply through the inferior mesenteric artery is impossible, it is important to preserve the blood supply through the internal iliac artery to prevent possible left-side colon ischemia [72].

Aortoenteric Fistula

An aortoenteric fistula is a connection between the aorta and the digestive tract. Primary aortoenteric fistula is a connection between the native aorta and the digestive tract. It occurs most often as a connection between an AAA and the duodenum [49].

Secondary aortoenteric fistula is a connection between the aortic reconstruction and the digestive tract and is one of the most serious complications in vascular surgery. It is observed in 1.6% of the cases [56]. A secondary aortoenteric fistula develops more often after the aortobifemoral bypass as compared to AAA resection. It is more common when performing end-to-side anastomosis as compared to end-to-end anastomosis [39]. The prosthesis communicates most commonly with the duodenum, rarely with the small intestine. The fistula results from direct contact between the prosthesis or pseudoaneurysm of the proximal anastomosis and the duodenum or the small intestine. The impaired integrity of the duodenal wall or the small intestine leads to the leakage of the intestinal contents and direct contact between the prosthesis and the digestive tract [56].

Aortoenteric fistula manifests itself as gastrointestinal bleeding. Bleeding may initially be episodic and minor; massive bleeding may occur later. If the patient develops the signs of gastrointestinal bleeding, possible aortoenteric fistula should be taken into account. It is not easy to make the diagnosis of aortoenteric fistula, since, in duodenoscopy, the source of bleeding may be not visualized [49]. The current reference standard for the diagnosis is CT which can visualize pathological formations in the area of the proximal anastomosis and the prosthesis. PET-CT may serve as an additional diagnostic method as it can visualize fistula localization. The patient may present with the symptoms of chronic sepsis, elevated levels of CRP and procalcitonin. Blood cultures are not always positive. Treatment is difficult. The

principle of treatment is the same as in treating prosthetic infection, namely intravenous antibiotic therapy, prosthesis extraction; resection of the affected area of the digestive tract [35].

There are two methods to exteriorize the prosthetic material:

- 1) to remove the prosthetic material, to suture the terminal aorta using blind suture, to provide the blood supply to the lower extremities by creating the extra-anatomic bypass, most often the axillofemoral bypass;
- 2) in situ reconstructions using the femoral vein or the arterial allograft.

However, because it is a case of highly virulent infection caused by gram-negative bacteria, the extra-anatomic bypass is safer. The use of in situ reconstructions alongside with antibiotic-loaded prosthesis is controversial. The mortality rate in the aortoenteric fistula is >50% [41]. To prevent aortoenteric fistula, it is necessary to carefully close the retroperitoneal space with sutures without leaving any direct contact between the prosthesis and the duodenum or the other part of the digestive tract [56].

Sexual Dysfunction

Sexual dysfunction may result from the impairment of the paraaortic hypogastric plexus during aortoiliac reconstructions. Symptoms of sexual dysfunction are present in 25% of men who underwent surgery [21]. The impairment of the paraaortic plexus manifests itself as retrograde ejaculation. Sexual dysfunction may also result in impaired blood supply to the internal iliac arteries that lead to erectile dysfunction.

COMPLICATIONS IN CAROTID ARTERY RECONSTRUCTIONS

Complications in carotid artery reconstructions may be:

- A) During carotid endarterectomy, stroke or TIA may occur at the stage of artery identification, artery clamping, intraoperative shunt placement, poor-quality or inadequate endarterectomy [75]. In all these cases, neurological impairment is embolic, and only anti-stroke therapy is required, which, in most cases, leads to complete or nearly complete relief of focal symptoms [28].

In thrombosis of the reconstructed area, emergency reintervention is required.

Thrombosis of the internal carotid artery (ICA) after carotid endarterectomy may be associated with the following factors:

- technical errors during the surgical intervention (narrowing of the vessel with a suture, suturing of the opposite wall, leaving off the unremoved portion of the plaque in the common carotid artery or the ICA, buckling of the intima in the distal ICA);
- cerebral hypoperfusion due to MI, heart arrhythmia, hypotension in blood loss or drug-induced hypotension;
- inadequate postoperative management (inadequate antiplatelet therapy, arterial hypertension).

In the case of re-surgery for thrombosis, it is crucial to follow the following recommendations:

- re-administration of heparin before artery clamping;
- a thorough revision of a distal ICA suture line;
- careful removal of the blood clot in the ICA by aspiration and extraction or using a Fogarty catheter.

B) Intracerebral hemorrhage is a very rare but very formidable complication. In most cases, it is fatal. Hemorrhagic stroke most commonly occurs a few days after surgery; in such complication, medical aid is limited to observations and some conservative recommendations, namely dehydration, maintenance of blood pressure within slightly below normal range, discontinuation of disaggregate or anticoagulant therapy [76].

Postoperative hemorrhage may be caused by:

- ischemic focus that developed after stroke;
- hyperfusion;
- severe arterial hypertension.

C) Local nerve injury (n. laryngeus recurens 6.5%, n. hypoglossus, n. mandibularis, n. laryngeus superior, n. facialis). In 80% of cases, nerve injury during carotid artery surgeries is transitory in nature with functional recovery up to 3-5 months [26].

D) Headache which may result from hyperfusion.

E) Ductus thoracic injury.

F) Central hyperthermia and uncorrected hyperglycemia that are signs of cerebral edema and malacia. This type of complications is mainly fatal [30].

VASCULAR ACCESS COMPLICATIONS IN PATIENTS WITH CHRONIC RENAL FAILURE

Thrombosis is the most common complication. Early thrombosis (from 1 to 7 days) is most commonly caused by technical errors when forming vascular access (narrowing of the anastomosis lumen or its inadequate diameter, vascular torsion, creation of the anastomosis close to the venous valve that impair the blood flow at the anastomosis site; inadequate mobilization of blood vessels, namely the deformation of excessively mobilized blood vessels, trauma to blood vessels during vascular mobilization, hematomas at the anastomosis site and within arteriovenous fistula). Persistent hypotonia and hypercoagulation in the postoperative period lead to arteriovenous fistula thrombosis as well. Up to 25% of arteriovenous fistulae become occluded in the early postoperative period. Late postoperative thrombosis accounts for 12-15% of the cases, and its incidence is determined by fistula dysfunction [77, 78].

Bleeding

The main causes of bleeding are inadequate hemostasis, high blood pressure, purulent and infectious complications, excessive heparin dosage, hypocoagulation.

Aneurysm

Arteriovenous aneurysm (Figure 15) usually develops due to a large diameter of the anastomosis, frequent vasopuncture in a certain area, proximal venous stenosis. This complication requires surgical correction of vascular access, namely anastomosis reconstruction, resection of the extended fistula segment.

Figure 15. Arteriovenous aneurysm.

Infection

Surgery is associated with a high risk of infection, since the terminal stage of chronic renal failure is characterized by significantly reduced patient's immunity. Purulent and inflammatory complications may account for 5% of the cases involving primary vascular access. The task of an angiosurgeon consists of early detection of this complication that will allow reducing the risk of erosive bleeding. If bleeding occurred, the vessels should be ligated in the intact zone. To prevent infection, broad-spectrum antibiotics should be prescribed in the postoperative period [79].

Vascular Access to Steal Syndrome

This complication results from steal syndrome and distal limb ischemia due to low perfusion pressure. Vascular access to steal syndrome develops most often when performing

the end-to-end anastomosis. In case of minor severity, there is no need for special treatment. In case of significant circulatory disorders in the distal limb, fistula elimination or the reconstruction of the anastomosis (end-to-end anastomosis) which allows eliminating steal syndrome are needed [80].

Complications Associated with Using Central Venous Catheters

Infectious Complications

The catheter itself or the space surrounding it may be the source of infection. To avoid infectious complications, it is necessary to follow all the rules of central venous catheter placement and maintenance [79].

Thromboembolic Complications

At the end of the catheter, large blood clots or thin fibrin layers can be formed. Large blood clots usually lead to change in the pressure curve and the difficulties when trying to get blood from the catheter or flushing it. The patients often develop limb swelling, and if the catheter was inserted through the internal jugular vein, neck pain or jugular vein distension might appear. In the case of venous catheter thrombosis, it must be removed or replaced.

AMPUTATION IN VASCULAR SURGERY

Despite the great achievements in modern angiology and angiosurgery, in 28-47% of the patients with critical ischemia, above-knee amputation of the lower extremity is the only surgery that relieves severe pain [81]. Vascular reconstructions not always result in quality limb revascularization. In 6-15% of the cases, the attempts to jugulate the phenomena of critical ischemia are unsuccessful, and surgeons have to perform limb amputation according to secondary indications [82]. The frequency of performing lower limb amputation in patients with vascular diseases is as follows: above-knee amputation – 39.1%, below-knee amputation – 23.6%, foot amputation – 6.4%, transmetatarsal amputation – 30.9% [81, 83].

Severe complications such as tissue necrosis and postoperative wound infection after below-knee amputation result in re-amputation at the above-knee level in approximately 50% of the patients [84].

Above-knee amputation causes patient's functional disability. Only 30.3% of the patients who underwent such surgery use the prosthesis successfully. After below-knee amputation, this number reaches 69.4% [85].

To determine treatment tactics for the patients with the ischemic ulceronecrotic lesions of the lower extremity, attention should be paid to the following factors [86]:

- I. whether there is a possibility to perform vascular reconstructions in the affected limb. The severity of the patient's general condition, the presence of comorbidities, the degree of the damage to the arterial limb bed are assessed;

- II. whether there is a possibility to perform organ-preserving surgery in the foot, including minor amputations (the spread of ulceronecrotic tissue lesions of the foot; nature and extent of purulent complications);
- III. the strategy and tactics of limb amputation are determined.

Classification of Amputations

Limb amputation is the traumatic or surgical removal of the peripheral part of the limb at the bone level.

Disarticulation (exarticulation) is the surgical removal of the peripheral part of the limb at the articulation level.

Foot resection is the surgical removal of the foot segment with one or more toes in the longitudinal direction.

Classification of Limb Amputations [87]

- according to indications – primary amputation, secondary amputation, re-amputation;
- according to terms of performing – emergency amputation, urgent amputation, and elective amputation;
- according to surgical tactics – one-stage surgery, two-stage surgery;
- according to the extent: minor amputation, major amputation;
- according to the method of tissue dissection: guillotine amputation, circular amputation, flap amputation, exarticulation of any limb segment;
- according to the method of stump formation – fascioplasmic amputation, tendoplasty amputation, myoplasty amputation, osteoplasty amputation.

The indications for primary limb amputation in acute and chronic occlusive vascular diseases is dry and wet gangrene of the peripheral segment (or segments) of the limb [88]. Secondary amputations are carried out according to secondary indications that include ineffective conservative long-term therapy if it is impossible to perform vascular reconstructions; failed surgical reconstruction of the great vessels in patients with severe pain [89].

Re-amputation is limb amputation at a higher level as compared to previously performed amputation [90]. The indications for re-amputations are purulent and necrotic complications in the postoperative period and severe pain with trophic changes in the stump. Minor amputations include amputations of the foot or hand at different levels. In patients with critical ischemia, minor amputations are possible only in the case of compensating distal blood flow [91].

Large amputations include amputations at any level of the shin, forearm or upper arm.

An absolute contraindication for limb amputation is the patient's agonal state [90].

Selection of Amputation Level

Amputation/exarticulation of a single toe, resection and distal amputation of the foot are performed in case of [87, 89]:

- preserved or restored blood supply to the lower third of the tibia;
- tibiofemoral index of > 0.6 ;
- the transcutaneous oxygen tension (Tcp02) value at the amputation level of > 30 mm Hg.

Below-knee amputation is performed in case of:

- the spread of ischemic and purulent foci to the lower end of the tibia as it is impossible to form the stump of the foot at the lowest level possible;
- preserved or restored blood flow through the deep femoral artery with a good filling in the area of the knee joint;
- the value of the gradient between the lower and the upper thirds of the tibia of <30 mm Hg;
- the Tcp02 value at the amputation level (a border between the lower and the upper thirds) of >30 mm Hg.

Above-knee amputation is performed in case of:

- it is impossible to preserve the tibia;
- preserved or restored blood flow through the common and deep femoral arteries;
- the value of the gradient between systemic (the upper arm) and segmental (the upper third of the thigh) blood pressure of <30 mm Hg;
- the Tcp02 value at the amputation level of >30 mm Hg.

Thigh disarticulation is performed in case of:

- it is impossible to perform above-knee amputation due to the presence of devitalized tissues on the posterior and outer surface of the upper third of the thigh;
- lack of main blood flow in all the arteries of the thigh;
- reduction in the Tcp02 value to <30 mm Hg at the level of the upper third of the thigh.

Finger amputation or disarticulation is performed in case of:

- the value of the gradient between the upper third of the contralateral (unaffected) upper arm and the lower third of the forearm of <30 mm Hg when measuring systemic blood pressure;
- preserved or restored blood supply to the lower third of the forearm;
- the Tcp02 value at the amputation level of >30 mm Hg.

Forearm amputation is performed in case of:

- the spread of ischemic and purulent foci to the forearm as it is impossible to form the stump of the hand;
- the value of the gradient between the lower third of the upper arm and the upper third of the forearm of <30 mm Hg when measuring segmental blood pressure;
- preserved or restored blood flow through the deep brachial artery with good perfusion in the elbow joint;
- the TcpO₂ value at the amputation level of >30 mm Hg.

Upper arm amputation is performed in case of:

- it is impossible to preserve the forearm;
- the value of the gradient between the affected and unaffected upper arm of <30 mm Hg when measuring systemic blood pressure;
- preserved or restored blood flow through the axillary artery;
- the TcpO₂ value at the upper arm amputation level of > 30 mm Hg.

Toe Amputation

Depending on the extent of the necrotic lesion, the following amputations are performed:

- toe amputation at the middle phalanx level;
- toe amputation at the proximal phalanx level;
- toe disarticulation;
- toe amputation according to Garengeot (removal of all the toes at the level of the metatarsophalangeal joints).

Foot Amputation and Resection

- surgical resection of the foot;
- Transmetatarsal amputation;
- Lisfranc (tarsometatarsal) amputation.

Marginal resection of the foot is surgical removal of the foot segment with one or more toes along the outer or inner edge.

Sectoral resection of the foot is surgical removal of the foot segment with one or more inner toes (II-IV)

Transverse foot resection is foot amputation.

Upper Limb Amputation

The indications for upper limb amputation include gangrene due to obliterative atherosclerosis (extremely rare), diffuse arteriovenous angiodysplasia accompanied by impaired macro- and microcirculation, trophic disorders, severe pain, impossible surgical correction of the blood flow, untreated forms of thromboangiitis obliterans [92]. In the ischemic ulceronecrotic lesions, upper limb amputations are performed with an attempt to preserve as much of the residual limb length as possible [93].

CONCLUSION

The patients with peripheral arterial disease are considered as high-risk patients. The severity of this category of patients is due to their polymorbidity, namely hypertension, cardiac pathology, diabetes mellitus, renal failure. An additional high-risk factor is smoking. Surgery may provoke the decompensation of chronic disease; therefore, it is important to minimize risk factors. In the preoperative period, preoperative preparation, risk stratification, and optimal drug therapy are necessary. During surgery, it is important to choose an optimal and adequate volume of surgery considering the patient's age and polymorbidity. In the postoperative period, intensive postoperative monitoring and early rehabilitation of the patient are of great importance. In the case of early postoperative complications, an adequate assessment of the patient's condition and emergency surgery, if necessary, are important. It is timely re-surgery that significantly reduces postoperative mortality rates in case of early postoperative complications. Centralization of vascular patients results in the reduction in postoperative complications.

Chapter 293

LAPAROSCOPIC SLEEVE GASTRECTOMY

Pablo Priego*, MD, PhD

Department of General Surgery, Division of Esophagogastric
and Bariatric Surgery, Ramón y Cajal University Hospital,
Madrid, Spain

ABSTRACT

Nowadays, laparoscopic sleeve gastrectomy is the most frequent bariatric procedure worldwide. However, and although this technique seems to be very simple, some important surgical details are essential in order to prevent potential severe complications after surgery. The aim of the chapter is to describe and show our standardized technique based on different surgical pictures.

Keywords: laparoscopic sleeve gastrectomy, surgical technique

INTRODUCTION

Nowadays, laparoscopic sleeve gastrectomy (LSG) has evolved since its beginnings, experiencing increasing popularity worldwide in comparison with other bariatric procedures like the Roux-en-Y gastric bypass and adjustable gastric banding [1].

The main reason of this popularity is not only because LSG is a less complex surgical technique, but also because it has demonstrated durable long-term weight loss and metabolic improvements in obese patients [2].

LSG was first conceived as a first step (restrictive component) of a two staged procedure that included a duodenal switch for high-risk patients [3].

Over time, as minimally invasive techniques advanced and surgical experience increased, the procedure was adopted as a first line treatment option for morbid obesity [4].

* Corresponding Author's Email: papriego@hotmail.com.

INDICATION

1. Primary weight loss procedure.
2. Initial stage of two-staged approach in superobese patients.
3. Component of laparoscopic biliopancreatic diversion with duodenal switch (BPD-DS) or Single anastomosis duodenoileal with sleeve gastrectomy (SADI-s).

PREOPERATIVE PREPARATION

The preoperative work-up for bariatric surgery is performed by a multidisciplinary team, including surgeons, endocrinologists, dieticians, gastroenterologists, anesthesiologists and psychiatrists, who combine a medical, nutritional, and endocrinology workup to evaluate potential surgical candidates.

Preoperative assessment included abdominal ultrasound, barium swallow, upper gastrointestinal endoscopy, analytic evaluation of the nutritional status and in selected cases a polysomnography, fibroscan, 24ph-metry and manometry.

ANESTHESIA

An enhanced recovery after surgery (ERAS) programme is followed with an opioid-free anesthesia. Central vein and bladder catheters were not used.

SURGICAL TECHNIQUE

Instrumentation

1. Three 12mm and one 5mm ports
2. Nathanson liver retractor
3. 30° scope
4. Harmonic scalpel
(Harmonic ACE; Johnson & Johnson)
5. Veress needle
6. Three atraumatic graspers
(one of the long size)
7. Suction irrigator
8. Echelon 60mm (gold and blue cartridges)
(Johnson & Johnson)
9. Peristrip-dry
10. Gauzes
11. Clip applicator (optional)

PATIENT, PORT AND SURGEON POSITIONS

a) Patient Position

Patients are placed on an operating table in supine position with legs and arms opened.

Intermittent pneumatic compression devices are used to help prevent blood clots in the deep veins of the legs. The legs and hips are secured with safety straps to prevent bowing or buckling of the knees or ankles.

No urinary catheter is needed. Patient is placed in anti-Trendelenburg position allowing the transverse colon and small intestine to fall in a caudal direction. An orogastric tube of 32Fr is placed into the stomach in order to calibrate the sleeve during stapling and transection (Figure 1).

Figure 1. Patient position.

b) Port Position

Pneumoperitoneum to a pressure of 12-14mm Hg is achieved through Veress needle technique at Palmer point in the left upper quadrant. A primary, 12-mm port is inserted at the junction of the upper two third and lower one third of the line joining the xiphoides to the umbilicus. This is the camera port. Two 12-mm working port are inserted in the left and right quadrant area in the midclavicular line. A 5-mm port is inserted in the epigastrium. A Nathanson liver retractor is used to retract the left lobe of the liver. Another 5-mm port is placed on the left in anterior axillary line at the level of the umbilicus. This is used by the second assistant on the left side. This is used mainly to retract the stomach or to lift it up (Figure 2).

c) Surgeon Position

The operating surgeon stands in the space between the legs of the patient.

The camera assistant is on the left of the operating surgeon. The first assistant surgeon stands on the right side of the operating surgeon.

Monitor is placed on the upper part of the patient for assistant and surgeon view (Figure 3).

Figure 2. Port position.

Figure 3. Surgeon position.

PROCEDURE

a) Identification of Angle of His

The dissection begins identifying the angle of His, taking down the fat pad which covers the upper part of the fundus. An important trick is to visualize the left crura of the diaphragm.

Once the crura is identified, gauze is placed between the fundus and the spleen.

Mobilizing this fat pad provides us with an adequate exposure of this area for optimal stapling and transection of the stomach.

If left crura of diaphragm is not easily visualized because of splenomegaly or an excess of fatty tissue of the patient, do not care and place the gauze in that space. Any hiatal hernias should be addressed at this time and repaired in a posterior fashion (Figure 4-10).

Figure 4. Identification of the angle of His.

Figure 5. Section of the fat pad.

Figure 6. Section of the fat pad until visualization of the left crura.

Figure 7. Visualization of the left crura.

Figure 8. Visualization of the left crura (continued).

b) Mobilization of Greater Curvature

Using the harmonic device, a window is made into the omental bursa approximately at the level of the incisura angularis because this place is easier to enter into the omental transcavity.

Figure 9. Placement of a gauze in the space between left crura and the spleen.

Figure 10. Placement of a gauze in the space between left crura and the spleen (continued).

Proceed superiorly sealing and dividing the short gastric vessels directly on the serosa of the stomach until the left crura and the gauze are visualized. Great care must be taken when dissecting and sealing the short gastric vessels because they are at high risk for intraoperative and postoperative bleeding. First assistant has to retract very carefully the greater omentum of patient to the left size of the abdomen and the left hand of the surgeon has to retract the stomach to the right size. Sometimes, and when there are several adhesions and the left crura cannot be visualized, the first assistant can take the posterior part of the fundus towards the patient's right side and thus inferiorly the surgeon has a better exposure of the cardias, spleen and left crura (Figure 11-26).

Figure 25. Division of the short gastric vessels. The section continues cranially until reaching the left crura (marked by the gauze placement).

Figure 26. Division of the short gastric vessels. The section continues cranially until reaching the left crura (marked by the gauze placement).

c) Mobilization of the Antrum

Once the left crura is identified, proceed with the division of greater omentum inferiorly towards the pylorus (4 - 6cm proximally to it) avoiding to injury the right gastroepiploic vessels and gastroduodenal artery (Figure 27-34).

d) Mobilization of the Posterior Part of Stomach

Mobilization of stomach finalized by taking down any associated adhesions between the stomach and the anterior-superior part of the pancreas until the left crura (Figure 35-36).

Figure 27. Division of greater omentum inferiorly towards the pylorus.

Figure 28. Division of greater omentum inferiorly towards the pylorus (continued).

Figure 32. Identification of the pylorus and measurement of 4-6 cm cranial to the pylorus to mark the limit of section of the greater omentum.

Figure 33. Division of greater omentum inferiorly towards the marked point 4-6cm cranial to the pylorus.

Figure 34. Division of greater omentum inferiorly towards the marked point 4-6cm cranial to the pylorus (continued).

e) Gastrectomy

Once the dissection is completed, a 32-French blunt-tipped bougie tube is slowly advanced under direct visualization to the level of the pylorus (Figure 37-40).

A 60mm gold cartridge is used to staple 4-6cm proximal to the pylorus (from 12mm trocar of right hypocondrium). We always reinforced all the cartridges with peristrip-dry. Before firing the stapler, the bougie tube must be visualized passing distal to the stapler along the lesser curvature.

Figure 35. Division of posterior adhesions to ease the pass of the bougie.

Figure 37. With the grasper in the left hand of the surgeon the bougie is directed towards the antrum, adjacent to the lesser curvature.

Figure 38. With the grasper in the left hand of the surgeon the bougie is directed towards the antrum, adjacent to the lesser curvature (continued).

Figure 39. With the grasper in the left hand of the surgeon the bougie is directed towards the antrum, adjacent to the lesser curvature (continued).

Figure 40. With the grasper in the left hand of the surgeon the bougie is directed towards the antrum, adjacent to the lesser curvature (continued).

Figure 41. Before firing the stapler, the bougie tube must be visualized passing distal to the stapler along the lesser curvature.

Figure 42. Before firing the stapler, the bougie tube must be visualized passing distal to the stapler along the lesser curvature (continued).

The second cartridge (60mm gold) is in proximity to the incisura angularis and care must be taken in order to avoid stenosis at this level.

Figure 43. Before firing the stapler, the bougie tube must be visualized passing distal to the stapler along the lesser curvature (continued).

Figure 44. Before firing the stapler, the bougie tube must be visualized passing distal to the stapler along the lesser curvature (continued).

Figure 45. The cartridge is reinforced with peristrips dry.

This second cartridge is also introduced through the 12mm trocar in right hypocondrium (Figure 41-46).

Figure 46. The cartridge is reinforced with peristrips dry (continued).

Following cartridges (60mm blue) are introduced through the 12mm trocar on left hypocondrium towards the upper part of the stomach. At this point it is critical to properly expose the anterior and the posterior aspect of the stomach using lateral traction (first assistant). This prevents a corkscrewing effect of the sleeve as well as avoiding leaving a large posterior fundus.

It is important to avoid stapling too close to the gastroesophageal junction because it is a vascular watershed area and damage could lead to ischemia and a higher leak rate (Figure 47-66).

Figure 47. the first 2 cartridges are introduced through the port on right hypochondrium. Following cartridges are introduced through the trocar on the left hypochondrium.

Figure 48. Following cartridges are introduced through the 12mm trocar on left hypochondrium towards the upper part of the stomach.

Figure 67. The first assistant performs a lateral traction to prevent from leaving a large posterior fundus (continued).

Figure 68. The presence of staple line bleeding is checked.

f) Checking the Staple Line

Once the sleeve is created, we have to check the absence of bleeding in the staple line (Figure 67- 69).

Figure 69. The presence of staple line bleeding is checked (continued).

If bleeding is observed, haemostasia with clips is performed. Finally, a methylene blue test is performed, excluding any spillage of blue contents into the peritoneal cavity. The orogastric tube is removed after the tightness test (Figure 70-72).

Figure 70. The presence of staple line bleeding is checked (continued).

Figure 71. The presence of staple line bleeding is checked (continued).

ABSTRACT

Laparoscopic Adjustable Gastric Banding (LAGB) is still a popular bariatric procedure that is minimally invasive and without irreversible anatomical changes, and although the indications have decreased in the last years it still has some indications. The aim of this chapter is to describe the surgical technique of LAGB.

Keywords: laparoscopic adjustable gastric banding, surgical technique

INTRODUCTION

Adjustable gastric banding was introduced as a bariatric procedure and rapidly spread for its simplicity and low morbidity [1]. Considered as a “pure restrictive” procedure, placing a band tightly around the stomach, this could not explain the weight loss and the action of the band. Activation of a peripheral satiety mechanism without physically restricting meal size has been proposed as a mechanism of action [2]. In the last years, there has been an important decrease in LAGB procedures, mainly attributed to doubts regarding its effectiveness in long-term results, but still is indicated in specific populations [3].

* Corresponding Author's Email: marta.cuadrado@salud.madrid.org.

INDICATION

Indication for Laparoscopic Adjustable Gastric Band (LAGB) are the same as any bariatric procedures.

A body mass index of at least 40 or 35 in association with any comorbidities.

A careful selection of patients should be made and a multidisciplinary approach is recommended.

Patients at lower BMI, at the extremes of age or with more significant co-morbidities, are potential candidates.

Long-term follow up is required after LAGB.

PREOPERATIVE PREPARATION

All patients should receive prophylaxis with cephalosporin intravenous before induction of anesthesia.

Anesthesia

General Anesthesia is required to perform the surgical procedure. Local Anesthesia is injected around laparoscopic ports at the end of the procedure.

SURGICAL TECHNIQUE

Instrumentation

1. One 15 mm trocar and three 5 mm ports
2. Liver retractor
3. 5mm 30° scope
4. Veress needle
5. Two atraumatic graspers
6. Finger
7. Lap-band

PATIENT, PORT AND SURGEON POSITIONS

a) Patient Position

The patient is placed in supine position. Fixation around the knees is needed to prevent sliding as the procedure requires a forced anti-Trendelenburg position.

Figure 1. Patient position.

b) Port Position

Pneumoperitoneum is made by inserting a Veress needle above the umbilicus until a pressure of 12-14 mm Hg is reached.

Then a 5mm port is inserted at the same place for the camera.

A 15mm port is placed in the right hypochondrium under direct vision to allow the band insertion.

Two 5mm ports are placed, one under the xiphoid for the liver retractor and the other in the left upper quadrant. (Figure 2).

Figure 2. Port position.

c) Surgeon Position

The surgeon stands in the right side of the patient, and the assistant stands on the left holding the camera and the liver retractor.

PROCEDURE

a) Band Preparation and Insertion

The band is prepared according the manufacturer's specifications.

Figure 3. Band preparation.

The band is inserted through the 15mm port.

Figure 4. Band insertion.

b) Pars Flaccida Opening

The procedure begins with the opening of the pars flaccida. Then the lesser curvature is retracted to the patient's left to expose the right crus of the diaphragm.

Figure 5. Opening of the pars flaccida.

Figure 6. Opening of the pars flaccida (continued).

Figure 7. The lesser curvature is retracted to the patient's left to expose the right crus of the diaphragm.

c) Tunnel Creation

Once the right crus has been identified, a minimal incision is made in the peritoneum in the lower aspect of the crus, to allow the passage of the finger.

Bluntly, a tunnel behind the stomach is created with the finger towards the His angle.

Figure 8. A minimal incision is made in the peritoneum in the lower aspect of the crus, to allow the passage of the finger.

Figure 9. A tunnel behind the stomach is created with the finger towards the His angle.

Figure 10. A tunnel behind the stomach is created with the finger towards the His angle (continued).

Figure 12. A tunnel behind the stomach is created with the finger towards the His angle (continued).

Figure 13. A tunnel behind the stomach is created with the finger towards the His angle (continued).

Figure 14. A tunnel behind the stomach is created with the finger towards the His angle (continued).

Figure 15. A tunnel behind the stomach is created with the finger towards the His angle (continued).

d) Band Placement

Carefully, the edge of the band is placed in the finger's eye, and with a minimal traction, the band is left behind the stomach.

Figure 16. The edge of the band is placed in the finger's eye, and with a minimal traction, the band is left behind the stomach.

Figure 17. The edge of the band is placed in the finger's eye, and with a minimal traction, the band is left behind the stomach (continued).

Figure 18. The edge of the band is placed in the finger's eye, and with a minimal traction, the band is left behind the stomach (continued).

Figure 19. The edge of the band is placed in the finger's eye, and with a minimal traction, the band is left behind the stomach (continued).

Figure 21. The edge of the band is placed in the finger's eye, and with a minimal traction, the band is left behind the stomach (continued).

e) Band Closure

When the band is in place, the tube is passed through the band buckle and close tight until it is secured.

Figure 22. The tube is passed through the band buckle and close tight until it is secured.

Figure 23. The tube is passed through the band buckle and close tight until it is secured (continued).

Figure 24. The tube is passed through the band buckle and close tight until it is secured (continued).

Figure 25. The tube is passed through the band buckle and close tight until it is secured (continued).

Figure 26. The tube is passed through the band buckle and close tight until it is secured (continued).

f) Band Fixation

The fundus is wrapped over the band and secured to the stomach pouch above by interrupted sutures.

Figure 27. The fundus is wrapped over the band and secured to the stomach pouch above by interrupted sutures.

Figure 28. The fundus is wrapped over the band and secured to the stomach pouch above by interrupted sutures (continued).

Figure 39. The fundus is wrapped over the band and secured to the stomach pouch above by interrupted sutures (continued).

Figure 40. The fundus is wrapped over the band and secured to the stomach pouch above by interrupted sutures (continued).

Figure 41. The fundus is wrapped over the band and secured to the stomach pouch above by interrupted sutures (continued).

Figure 42. The fundus is wrapped over the band and secured to the stomach pouch above by interrupted sutures (continued).

g) Port Placement

The tip of the band is grasped and pulled out through the 15mm trocar.

The liver retractor is then removed as so are the ports under direct vision to detect any bleeding. Local anesthesia is placed under vision. The pneumoperitoneum is released.

The band is connected to the port, and a pocket just above or under the port incision is created until the fascia is exposed. Three non-absorbable sutures are placed for the port fixation.

h) Closure

5 mm ports are closed with non absorbable 5/0 suture.

15mm port is closed with absorbable intradermic suture.

ABSTRACT

Gastroesophageal reflux (GERD) is considered a disease related to morbid obesity whose incidence in obese population varies between 30 - 50%. Obese patients with GERD are not good candidates for anti-reflux procedures because of a high incidence of failure.

Despite the advantages of laparoscopic sleeve gastrectomy (LSG), it is associated with a postoperative GERD rate of 10 to 20%, regardless of preoperative diagnosis. For this reason, in obese patients with GERD, the Roux-en-Y gastric bypass (RYGB) is considered the gold standard, although several studies suggest that the association of hiataloplasty and/or fundoplication with LSG can guarantee a reduction of the postoperative ERGE, which varies from 20 to 34%.

Keywords: nissen - sleeve gastrectomy, fundoplication, gastroesophageal reflux, surgical technique

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a common clinical problem of the digestive tract, with an incidence of 30 - 50% in obese patients. Because obesity is a risk factor for the development of GERD, the increasing prevalence of obesity worldwide has coincided with the increased prevalence of GERD. Laparoscopic Nissen fundoplication is an effective treatment for patients with severe GERD and has a sustained long-term benefit [1-7].

Several authors believe that Nissen laparoscopic fundoplication may be an obstacle to the application of bariatric surgery in the treatment for morbidly obese patients with GERD [8]. However, there is a growing group of bariatric surgeons who believe that a fundoplication associated with LSG is an excellent technique for the control of GERD with good weight loss control. It is a technique that must also be taken into account in cases where there is duodenal or intestinal pathology, in which gastric bypass is not indicated.

INDICATION

1. Primary weight loss procedure.
2. Obese patients with esofagitis, GERD or Barrett's esophagus
3. Obese patients with GERD with any intestinal disease or structural lesions of the gastric or duodenal mucosa in which a RYGB would not be advisable.

PREOPERATIVE PREPARATION

In the case of this technique, in addition to the preoperative assessment of a multidisciplinary team, made up of various medical specialties involved in the treatment of morbid obesity (endocrinology, pulmonology, psychiatry, nutritionist, surgery), it is important to conduct a functional study of the esophagus and endoscopic and radiological study of the esophagogastrroduodenal tract (upper gastrointestinal endoscopy, barium swallow GI transit, 24-hours ph-metry and manometry)

Anesthesia

An enhanced recovery after surgery (ERAS) programme can be followed with an opioid-free anesthesia. Central vein and bladder catheters are not necessary.

SURGICAL TECHNIQUE

Instrumentation

At our institution we used the following surgical matherial for this technique:

1. Two 12mm, one 11mm and one 5mm ports
2. Liver retractor
3. 30° scope
4. Harmonic scalpel (Harmonic ACE; Johnson & Johnson)
5. Veress needle
6. Two traumatic clinch
7. Suction-irrigator

8. Non-absorbable sutures of Ethibond® 2.0 (Johnson-Johnson Inc. US)
9. Echelon 60mm (golden cartridges) (Johnson & Johnson, USA)
10. Staple-line reinforcement material
11. Gauzes
12. Clip applicator (optional)

PATIENT, PORT AND SURGEON POSITIONS

a) Patient Position

Patients are placed on an operating table in supine position with legs opened and the right arm opened.

Figure 1. Patient position.

Intermittent pneumatic compression devices are used to prevent thromboembolic events. The legs and hips are secured with safety straps. Once all the ports are inserted, the patient is placed in anti-Trendelenburg position. An orogastric tube of 38 - 40 Fr is placed into the stomach in order to calibrate the sleeve and the fundoplication during stapling and transection (Figure 1).

b) Port Position

Pneumoperitoneum to a pressure of 12 - 14mmHg is achieved through Veress needle technique or using the optical trocar. A primary, 11-mm port is inserted at the junction of the upper two thirds and lower one third of the line joining the xiphoides to the umbilicus. This is the camera port.

Two 12-mm working ports are inserted in the left and right quadrant areas at the level of the midclavicular line.

Figure 2. Port position.

A 5-mm port is inserted in the epigastrium. A liver retractor is used to retract the left lobe of the liver.

Another 5-mm port is placed on the left side in anterior axillary line at the level of the umbilicus. This is used by the first assistant on the left side to retract the stomach or to lift it up (Figure 2).

c) Surgeon Position

The operating surgeon stands in the space between the legs of the patient. The camera or 1st assistant is on the right of the operating surgeon. The scrub nurse stands on the right side of the 1st assistant.

Monitor is placed on the upper part of the patient for assistant and surgeon view (Figure 3).

Figure 3. Surgeon position.

PROCEDURE

a) Identification of the Angle of His

The dissection begins identifying the angle of His. A trick is to visualize the left crura of the diaphragma.

If there is a large fat patch, a careful resection is recommended (Figure 4-6).

Figure 4. The dissection begins identifying the angle of His.

Figure 5. The dissection begins identifying the angle of His (continued).

Figure 6. The dissection begins identifying the angle of His (continued).

b) Revision of the Hiatus

In this technique, it is crucial to check the esophageal hiatus to dissect and reduce a hiatal hernia when present. Therefore, the hiatus should be approached by the left crura, already dissected at the beginning of the surgery, and by the right crura, dividing the pars flacida of the lesser omentum. The right crura must be clearly identified and the hernia sac dissected (Figure 7-12).

An aid can be the passage under the esophagus of a tape or a silicone handle, which the first assistant must displace caudally, to be able to finish the dissection of the hiatus; the abdominal esophagus must be distally descended at least 5cm below the crus and all the anterior and the posterior esophageal hiatal space must be correctly dissected (Figure 13-16).

Figure 7. The hiatus should be approached by the left crura.

Figure 8. Division of the pars flacida of the lesser omentum.

Figure 9. Division of the pars flacida of the lesser omentum (continued).

Figure 10. Division of the pars flacida of the lesser omentum. Identification of the right crura.

Figure 11. Division of the pars flacida of the lesser omentum. Identification of the right crura (continued).

Figure 12. Dissection of the posterior part of the hiatus and performance of a retroesophageal tunnel.

Figure 13. A silicon handle is passed through the retroesophageal tunnel.

Figure 14. Left lateral traction is done for correct dissection of the posterior part of the hiatus and left crura.

Figure 15. Anterior dissection of the left crura.

Figure 16. Complete dissection of the hiatus.

It is advisable to close the esophageal hiatus before calibrating it with a 38 - 40 Fr orogastric tube, in order to avoid narrowness that may cause dysphagia (Figure 17). The hiatal orifice must be closed by 1 or 2 non-absorbable simple stitches of Ethibond® 2.0 suture (Figure 18-19).

Figure 17. Closure of the hiatus with 1-2 simple stitches.

Figure 18. Closure of the hiatus with 1-2 simple stitches (continued).

Figure 19. Closure of the hiatus with 1-2 simple stitches (continued).

c) Mobilization of Greater Curvature

The initial point of beginning the gastrolisis is about 5-6 cm from the pylorus at the level of the incisura angularis.

Using the harmonic scalpel, a window is opened into the omental bursa approximately at this level to enter into the omental transcavity (Figure 20-22).

The dissection continues cranially, dividing the short gastric vessels directly on the serosa of the stomach until reaching the left crura (Figure 23-26).

The first assistant has to retract very carefully the greater omentum to the left side of the abdomen and the left hand of the surgeon must retract the stomach to the right side, in order to ease the division of the short gastric vessels close to the left crura (Figure 27-29).

Figure 20. Gastrolisis begins about 5-6 cm from the pylorus at the level of the incisura angularis.

Figure 21. Gastrolisis begins about 5-6 cm from the pylorus at the level of the incisura angularis (continued).

Figure 22. A window is opened into the omental bursa.

Figure 23. Entrance into the omental transcavity.

Figure 24. Division of the short gastric vessels cranially.

Figure 25. Division of the short gastric vessels cranially (continued).

Figure 26. Division of the short gastric vessels cranially (continued).

Figure 27. Division of the short gastric vessels cranially (continued).

Figure 28. Division of the short gastric vessels cranially (continued).

Figure 29. Division of the short gastric vessels cranially (continued).

It is necessary to dissect thoroughly the gastric fundus from the left crura in order to avoid leaving a large posterior fundus. The splenic artery is close to this area and careful dissection must be performed to prevent from its damage (Figure 30).

Figure 30. Dissection of the gastric fundus from the left crura to avoid leaving a large posterior fundus.

Figure 31. The orogastric tube is progressed completely until its end is positioned in the antrum.

Figure 32. The orogastric tube is progressed completely until its end is positioned in the antrum.

Figure 33. A short Nissen valve is performed.

Once dissected and released the stomach from its adhesions, even on its posterior surface, the orogastric tube is progressed completely until its end is positioned in the antrum. This bougie is useful to calibrate the sleeve and the fundoplication (Figure 31).

Figure 34. A short Nissen valve is performed (continued).

Figure 35. The Nissen valve is fixed with simple stitches.

d) Fundoplication

A short Nissen valve of approximately 3cm is created using 3 Ethibond®3.0 sutures; the cranial stitch is fixed to the superficial muscular layer of the esophagus (Figure 32-40).

Figure 36. The Nissen valve is fixed with simple stitches (continued).

Figure 37. The cranial stitch is fixed to the superficial muscular layer of the esophagus.

Figure 38. The Nissen valve is fixed with simple stitches (continued).

Figure 39. The Nissen valve is fixed with simple stitches (continued).

Figure 40. The Nissen valve is fixed with simple stitches (continued).

e) Gastrectomy

Once the fundoplication is completed, a 60mm gold reinforced cartridge is used to staple 4-6cm proximal to the pylorus (from the 12mm trocar on right hypocondrium).

There are some authors who prefer not to use staple line reinforcement. Before firing the stapler, the bougie tube must be visualized passing distal to the stapler along the lesser curvature (Figure 41-43).

The second cartridge (60mm gold reinforced) is in proximity to the incisura angularis and care must be taken in order to avoid stenosis at this level.

This second cartridge also enters through the 12mm trocar on right hypocondrium (Figure 44-46).

Figure 41. The gastrectomy begins at the level of incisura angularis.

Figure 42. The first cartridge is inserted through the port placed in right hypocondrium.

Figure 43. The second cartridge is in proximity to the incisura angularis and care must be taken in order to avoid stenosis at this level.

Figure 44. The stapling continues cranially until reaching the fundoplication.

Figure 45. The stapling continues cranially until reaching the fundoplication (continued).

Figure 46. The stapling continues cranially until reaching the fundoplication (continued).

The division of the stomach must reach a balance between not stenosing the valve and not leaving excessive fundus.

Therefore, a stapling with reinforced golden load 60mm is made (Figure 47-49).

Figure 47. The stapling continues cranially until reaching the fundoplication (continued).

Figure 48. Staple line check.

Figure 49. Staple line check (continued).

Figure 50. Tightness test.

f) Checking the Staple Line

Once the sleeve is created, we have to check the absence of bleeding in the staple line. If bleeding is observed, haemostasia with clips is carried out. Finally, a methylene blue dye test is performed, excluding any spillage of blue contents into the peritoneal cavity. The orogastric tube is removed after methylene blue test (Figure 50-52).

Figure 51. Tightness test (continued).

Figure 52. Tightness test (continued).

Surgical drains are not necessary unless there is high concern for bleeding or leak.

The excluded stomach is then removed through the 12-mm port site (left hypocondrium) under direct visualization without bag.

ABSTRACT

Laparoscopic Roux-en-Y gastric bypass (LRYGB) is the gold standard bariatric procedure. There are many different techniques described. Regardless of the technique used, the LRYGB has excellent outcomes. The aim is to describe our standardized technique with a linear stapled gastrojejunal anastomosis, antecolic Roux limb, and stapled jejunojejunostomy with closure of the intestinal openings with hand sewn knotless unidirectional barbed suture.

Keywords: morbid obesity, bariatric surgery, laparoscopic Roux-en-Y gastric bypass, surgical technique, stapled anastomosis, barbed suture

INTRODUCTION

First laparoscopic Roux-en-Y gastric bypass (LRYGB) was described by Wittgrove et al., in 1994 [1]. Nowadays, LRYGB is the second most common bariatric procedure performed worldwide (30.1%) after sleeve gastrectomy [2]. It is a mixed technique with restrictive and malabsorptive components. In addition, several hormonal mechanisms are involved in weight loss. LRYGB remains the gold standard against which other bariatric techniques are measured because of the very low morbidity and mortality associated good long-term results

(maintained weight loss and obesity-related comorbidities resolved) and excellent quality of life.

Over time, the technique has evolved with several variations with regard the formation of the pouch and the reconstruction of gastrointestinal continuity.

INDICATIONS

1. Body mass index (BMI) ≥ 40 kg/m².
2. BMI 35-39,9 kg/m² with obesity-related comorbidities or gastroesophageal reflux disease.
3. Metabolic surgery. Patients with BMI 30-34,9 kg/m² and uncontrolled type 2 diabetes mellitus or metabolic syndrome.
4. Sweet eaters. In these patients restrictive operations should be avoided. After the LRYGB there is an initial refusal of sweets and a reduce intake in the long term, especially if dumping syndrome exists.
5. Failure of a previous restrictive bariatric operation. When a restrictive technique fails, should not be substituted by other restrictive operation. In this case, LRYGB is the most indicated option.

PREOPERATIVE PREPARATION

Potential candidates should undergo a multidisciplinary evaluation. Preoperative work-up includes abdominal ultrasound, upper gastrointestinal endoscopy, *Helicobacter pylori* testing, psychiatric assessment, laboratory with hormonal study, densitometry and polysomnography in patients with obstructive sleep apnea. All patients are referred to preoperative respiratory rehabilitation. Preoperative weight loss and smoking cessation are highly recommended. Pregnancy avoidance for 12 to 18 months postoperatively is counselled.

Anaesthesiologist analyzes related risk factors (comorbidities, medication). An enhanced recovery after surgery (ERAS) programme is followed in our hospital, as well as an opioid-free anaesthesia. Central venous line and urinary catheter are not used. Our patients routinely receive antibiotic prophylaxis and preoperative thromboembolic prophylaxis with low-molecular-weight heparin the night before the surgery.

The abdomen is prepped and draped in standard sterile fashion.

SURGICAL TECHNIQUE

Equipment

1. Two 12 mm optic trocars, one 11 mm trocar and one 5 mm trocar.
2. Nathanson liver retractor.
3. Camera and a 10 mm, 30-degree angled laparoscope.
4. Two monitors.

5. Harmonic scalpel (Harmonic ACE; Johnson & Johnson).
6. Two graspers and two atraumatic graspers.
7. Suction irrigator.
8. Endostapler: Echelon 60 mm (white and blue cartridges) (Johnson & Johnson).
9. Clip applier.
10. 36 French bougie tube.

PATIENT, PORTS AND SURGEON POSITIONS

a) Patient Position

Patient is positioned supine on the operating table with the legs and the right arm abducted (Figure 1). Appropriated sized intermittent pneumatic compression devices are used on both lower extremities. The legs and hips are secured with safety straps to prevent sliding, bowing or buckling of the knees or ankles. No Foley catheter is needed. A 15-20° reverse Trendelenburg position facilitates the exposition of the angle of His and displaces the transverse colon and small intestine inferiorly in a caudal direction.

Figure 1. Patient position.

b) Team Position

The operating surgeon stands in the space between the patient's legs. Surgeon's position should be ergonomic with shoulders relaxed and the forearms at a $\geq 90^\circ$ angle from the arms. The assistant surgeon is on the patient's left side. The nurse stands on the left side of the operating surgeon (Figure 2). Two monitors are placed at the level of the head and on the right side of the patient respectively.

Figure 2. Team position.

c) Pneumoperitoneum and Port Placement

Pneumoperitoneum can be achieved with Veress needle, open Hasson trocar or with an optical view trocar. Firstly, we use a 12 mm bladeless optical view trocar (Figure 3) inserted in the left upper quadrant at Palmer's point (3 cm below the left costal margin on the midclavicular line) (Figure 4). The remaining trocars are inserted under direct visualization. An 11 mm port (camera port) is inserted at the junction of the upper two thirds and lower one third of the xyphoumbilical line (the placement varies depending on the patient's shape). After this port is placed, the peritoneal cavity is inspected to exclude adhesions and any injury caused by the optical trocar. Another 12 mm working port is inserted in the right upper quadrant at the midclavicular line. In the epigastrium, a Nathanson retractor is used to retract the left lobe of the liver. Finally, a 5 mm port is placed at the left anterior axillary line (Figure 5). This port is used by the assistant, mainly to retract the stomach. Pneumoperitoneum pressure is established at 12-14 mm Hg.

Figure 3. Optical view trocar.

Figure 4. Optical trocar insertion at Palmer's point.

Figure 5. Ports position.

PROCEDURE (SURGICAL STEPS)

a) Identification of the Angle of His

Dissection is begun with Harmonic scalpel. Cardia's attachments to the diaphragm are divided and the fat pad at the upper part of the fundus is taken down. In this way, the angle of His and the left diaphragmatic crura is identified and a gauze is left between the fundus and spleen (Figure 6). If a hiatal hernia is addressed, it should be repaired closing diaphragmatic pillars with interrupted stitches.

Figure 6. Angle of His dissected with Harmonic scalpel.

b) Creation of the Gastric Pouch

In RYGB a gastric pouch (30 cm³) from the proximal stomach has to be created. The stomach is pulled laterally by the assistant. Access to the retrogastric space is achieved through a window performed with the harmonic scalpel at the lesser curvature, 6 cm measured from the cardia (Figures 7 and 8).

Figure 7. Window performed with the harmonic scalpel close to the gastric wall.

Figure 8. Access to the lesser sac.

Blood supply to the gastric pouch from the left gastric vessels has to be preserved. The stomach is transected horizontally from the lesser curvature using a 45 mm blue load linear endostapler (Figures 9 and 10). Before firing the nasogastric tube has to be removed by the anaesthesiologist.

Figure 9. Horizontal gastric transection with blue cartridge stapler.

Figure 10. Retrogastric space.

Retrogastric dissection is completed dividing any attachments to ensure that the gastric pouch is not created too large (Figure 11).

Figure 11. Retrogastric attachment division until reaching the left crus and gauze.

Figure 12. First vertical blue stapler.

The gastric pouch is calibrated with a 36 F bougie. The assistant retracts the stomach laterally to avoid redundancy, and a vertical linear stapling is performed (60 mm blue cartridges) (Figures 12, 13 and 14). Care must be taken to avoid firing too close to the esophageal junction.

Figure 13. First vertical blue stapler.

Figure 14. Usually a second staple is needed.

Figure 15. Second vertical staple firing toward the angle of His along the 36 F bougie.

c) Gastrojejunal Anastomosis

The greater omentum is divided (Figures 16 and 17) and the ligament of Treitz is exposed elevating the transverse colon (Figure 18).

Figure 16. Division of greater omentum with harmonic scalpel, starting close to transverse colon.

Figure 17. Split omentum.

Figure 18. Ligament of Treitz.

From the ligament of Treitz, 60 cm of jejunum are measured distally and the jejunal loop is brought up toward the gastric pouch ascending in an antegastric and antecolic fashion (Figure 19). Managing intestinal loops, atraumatic graspers are recommended.

Figure 19. Jejunal loop ascent, anterior to the transverse colon and the remaining stomach.

In selected cases, is helpful a tension-free stitch between the jejunum and the vertical stapled line in the gastric pouch (Figure 20).

Figure 20. Extracorporeal stitch (Ethibond 2/0) joining the gastric pouch and jejunum.

While the assistant holds the jejunal loop, enterotomies with the harmonic scalpel are performed in the gastric pouch and jejunum (Figures 21 and 22).

Figure 21. Enterotomy in the posterior wall of the gastric pouch, close to the horizontal stapled line.

Figure 22. Enterotomy in the antimesenteric border of the jejunum.

White load 60 mm linear endostapler is inserted through the 12 mm port located in the right upper quadrant. Jaws are inserted in both enterotomies to create a gastrojejunal anastomosis 3 cm in length (Figure 23).

Figure 23. Side to side gastrojejunal anastomosis with white cartridge, inserting only 3 cm before firing.

We close the intestinal opening with hand-sewn knotless unidirectional barbed suture starting at the left corner (Figures 24, 25 and 26).

Figure 24. Closure of the intestinal opening with knotless absorbable 2/0 barbed suture. Loop at the beginning of the suture avoids knot tying.

Figure 25. Unidirectional running suture from left to right.

Figure 26. Single-layer full-thickness suture (from down to up).

Continuous suture is finished by taking two additional bites in an opposite direction beyond the end of the enterotomy incision (Figure 27).

Figure 27. Last stitch in the opposite direction.

When gastrojejunal anastomosis is finished and to prevent the pouch from twisting, a stitch from jejunum (few centimeters distal to the gastrojejunostomy) to the remaining stomach is optional (Figure 28).

Figure 28. Stitch from the jejunum to the gastric remnant to prevent from anastomotic twisting.

d) Jejunojeunal Anastomosis

150 cm of small intestine are measured from the gastrojejunostomy to be used as the Roux limb (alimentary limb). In patients with BMI greater than 50 kg/m² alimentary limb could be longer than 150 cm. Two antimesenteric holes are performed with harmonic scalpel: one in the alimentary limb (Figure 29) and another in the biliopancreatic limb, few centimeters away from the gastrojejunostomy (Figure 30).

Figure 29. Enterotomy in the antimesenteric border of the small intestine (alimentary limb).

Figure 30. Antimesenteric enterotomy in the biliopancreatic limb.

A white load 60 mm linear stapler is inserted through both enterotomies (Figure 31) and then, a side to side jejunojunctionostomy is performed (Figure 32).

Figure 31. Cartridge introduction through both enterotomies.

Figure 32. Mechanical side to side jejunojejunostomy.

Intestinal opening is closed with hand-sewn knotless unidirectional barbed suture in the same way as described in the gastrojejunostomy (Figure 33). Suture is extended to close the mesenteric gap.

Figure 33. Closure of the intestinal opening in jejunojejunostomy with knotless unidirectional barbed suture.

Finally, a white linear stapler is fired in the jejunum between gastrojejunostomy and the jejunojejunostomy to disconnect both anastomoses (Figure 34).

Figure 34. Jejunal section.

e) Checking the Anastomoses and Stapled Lines

Once the bypass is created, the gauze is removed. We have to rule out any bleeding in the stapled lines. If bleeding is observed, haemostasia with clips should be performed. Finally, a methylene blue test is performed, excluding any leakage of blue contents into the peritoneal cavity. Routinely surgical drain is not necessary unless there is high a concern for bleeding or anastomotic leak.

Chapter 297

LAPAROSCOPIC ROUX-EN-Y GASTRIC BYPASS: CIRCULAR ANASTOMOSIS

Maria Posada*, MD, Gabriel Salcedo, MD,

Jose Ramon Torres, MD and Peter Vorwald, MD, PhD

Department of General Surgery, Division of Esophagogastric and Bariatric Surgery,
Fundación Jimenez Diaz University Hospital, Madrid, Spain

ABSTRACT

Roux-en-Y gastric bypass is considered the gold standard of surgical bariatric procedures and one of the most commonly performed worldwide.

The aim of the chapter is to describe our standardized technique illustrated by surgical pictures.

Keywords: laparoscopic Roux-en-Y gastric bypass; circular anastomosis; surgical technique

INDICATIONS

1. Primary weight loss procedure.
2. As a bariatric procedure in cases of contraindication for sleeve gastrectomy (esophageal reflux disease, Barrett's esophagus, paraesophageal hernia, severe gastric metaplasia...).

* Corresponding Author's Email: posada.maria@googlemail.com.

PREOPERATIVE WORK-UP

A multidisciplinary team, including surgeons, endocrinologists, dieticians, psychiatrists, psychologists, pulmonologists, gastroenterologists and anesthesiologists, performs preoperative work-up.

Abdominal ultrasound, upper gastrointestinal endoscopy and lab analysis including nutritional status, polysomnography and echocardiogram are routinely performed.

Monthly, a bariatric committee discusses challenging cases.

Only when the multidisciplinary bariatric committee considers that patient is suitable for surgery, the procedure is planned.

Anesthesia

An enhanced recovery after surgery (ERAS) protocol is followed. Arterial catheter to monitor blood pressure and one large peripheral line are inserted. Opioid-free anesthesia is usually performed. Central venous line, nasogastric tube and bladder catheters are not routinely used.

SURGICAL TECHNIQUE

Instrumentation

1. Three 12 mm and two 5 mm ports
2. 30° Scope
3. Veress needle
4. Vessel sealing device (Ligasure™ Maryland, Medtronic™)
5. Suction irrigator
6. Hook
7. 3 laparoscopic dissectors (two 31 cm and one 45 cm long)
8. 3 laparoscopic forceps (two 31 cm and one 45 cm long)
9. 3 atraumatic graspers (one 31 cm and one 45 cm long)
10. 2 Babcock forceps (one 31 cm and one 45 cm long)
11. Adler laparoscopic liver retractor
12. Ligaclip
13. Linear stapling device (Endo GIA™ Ultra 12 mm Universal Stapler, Covidien™).
White, blue and golden cartridges (45 and 60 mm, Covidien™)
14. Circular stapling device (EEA™ DST XL 25mm, 3.5 mm, Covidien™)
15. Orogastric Circular Anvil (EEA™ Orvil 25mm, Covidien™)
16. Gauzes
17. 2/0 braided non-absorbable suture (Ethibond™)
18. Surgical skin marker's tip
19. Laparoscopic knot tying device

PATIENT, PORT AND OPERATING STAFF POSITION

a) Patient Position

The patient is placed on the operating Table in the gynecological position.

The left arm is opened, while the right one should be closed if possible to avoid contact with the liver retractor's holder. The legs are placed on flexible boot stirrups (Figure 1)

A strap fastens on the waist below the umbilicus, to avoid the slipping of the patient while on Trendelenburg's position. Intermittent pneumatic compression devices are needed in order to decrease the risk of deep vein thrombosis. A urinary catheter is not necessary. The laparoscopy tower is placed near the patient's right shoulder.

Figure 1. Patient's position.

b) Port Placement

- 5mm port, in the upper right abdomen (liver retraction)
- 5mm port, in the upper left abdomen (1st assistant)
- 12mm port, 10-15 cm below the xiphoid (camera)
- 5mm port, in the right middle abdomen (left-hand surgeon)
- 12mm port, in the left middle abdomen (right-hand surgeon)

Access to the peritoneal cavity is obtained with a Veress needle. The puncture site is located in the upper left abdomen, near the costal margin. An intraperitoneal pressure of 15 mm Hg is achieved.

Usually a 10 mm 30° video laparoscope is used; when a 5 mm 30° video laparoscope is used, the camera port is replaced by a 5 mm port. (Figures 2-5)

Figure 2. Access to the peritoneal cavity is obtained with a Veress needle.

First, a 12-mm port is inserted, in the left upper abdomen, in the midclavicular line below the Veress needle insertion point; this is the surgeons, right-hand working port (Figure 3).

Figure 3. A 12-mm port is inserted, in the left upper abdomen.

All the other ports are placed in a line (at the same level, 10-15 cm distal to the xiphoid) (Figures 4, 5).

Figure 4. Placement of the ports.

Figure 5. Placement of the ports.

c) Staff Position in the Operating Room

- Gynecological position
- Surgeon between the patient's legs
- 1st assistant on the patient's left side
- 2nd assistant on the patient's right side
- Monitors are placed above the head and one in each side of the patient if available (Figure 6)

Figure 6. Staff position in the operating room.

PROCEDURE

a) Jejunio-Jejunostomy

Greater omentum and transverse colon are retracted cephalad until the Treitz's ligament is exposed. Gentle traction is applied on the first jejunal limb to clearly identify it, using an atraumatic grasper (Figure 7)

Figure 7. Identification of the angle of Treitz.

Next, we usually use a 70 cm biliary limb. To avoid any kind of technical errors, a stitch is placed between the greater curvature of the stomach and the antimesenteric border of the jejunum, 70 cm distal to the angle of Treitz (Figure 8).

Figure 8. A stitch is placed between the greater curvature of the stomach and the antimesenteric border of the jejunum, 70 cm distal to the angle of Treitz.

Using a skin marker's tip held to a dissector, the biliary limb is marked (Figure 9).

Figure 9. The biliary limb is marked.

150 cm of alimentary limb are measured, and a second stitch is placed between the alimentary limb and the biliary limb (Figure 10).

Figure 10. A second stitch is placed between the alimentary limb and the biliary limb.

A side-to-side jejunostomy is performed between the alimentary and biliary limbs, using a white 60 mm cartridge of the Endo GIA™ linear stapling device (Figure 11).

The remaining ostium is closed with interrupted 2/0 Ethibond™ stitches, which are knotted extracorporally (Figure 12).

Figure 11. A side-to-side jejunostomy is performed between the alimentary and biliary limbs.

Figure 12. The remaining ostium is closed with interrupted stitches.

b) Gastric Pouch

The patient is placed on a deep anti-Trendelenburg position. Adler retractor is placed through the port in the upper right abdomen, under the posterior surface of the left lobe of the liver, to properly expose the hiatus and the gastroesophageal junction (Figure 13)

Figure 13. Placement of the Adler retractor.

By pulling the fat pad on the gastroesophageal junction and widely pulling down the fundus, the left crus is exposed and dissected using blunt dissection. Once its base is reached, a gauze is placed there so it can be seen while performing the vertical division of the stomach (Figure 14)

Figure 14. A gauze is placed on the gastroesophageal junction.

The creation of the gastric pouch starts by using the hook to divide the visceral peritoneum. The vessel-sealing device is then used to dissect the hepatogastric ligament right on the lesser curvature of the stomach until the posterior surface of the stomach is reached. (Figures 15-18)

Figure 15. Dissection of the lesser curvature.

Figure 16. Dissection of the lesser curvature (continued).

Figure 17. Dissection of the lesser curvature (continued).

Figure 18. Dissection of the lesser curvature (continued).

The horizontal division of the stomach is done with a 45 mm blue cartridge of the linear stapling device (EndoGIA™). (Figure 19)

Figure 19. Horizontal division of the stomach.

The vertical division of the stomach is performed with one or two 45 mm golden cartridges of the linear stapling device (EndoGIA™), once it is checked that the lesser sac is free of adhesions (Figures 20, 21)

Figure 20. Vertical division of the stomach.

Figure 21. Vertical division of the stomach (continued).

At this point, the goal of the dissection is to find the gauze's tip, placed on the base of the left crura (Figures 22-24).

Figure 22. Dissection of the posterior face of the stomach.

Figure 23. Dissection of the posterior face of the stomach (continued).

Figure 24. Dissection of the posterior face of the stomach (continued).

The stomach is finally divided using a curved-tip 60 mm golden cartridge of the linear stapling device. Eventually another 45 mm golden cartridge is necessary (Figures 25, 26).

Figure 25. The stomach is finally divided.

Figure 26. The stomach is finally divided (continued).

Once the pouch is divided, this part of the procedure is completed. (Figure 27)

Figure 27. Division of the pouch from the gastric remnant.

c) Positioning the Orvil Device

We usually perform a circular stapled gastrojejunal anastomosis using the DST Series™ EEA™ XL 25mm EEA™ 3.5 stapling device (Figure 28).

Figure 28. Orvil device.

Once the gastric pouch is completed the anesthesiologist passes the orogastric tube (OrVil™ 25mm device) through the esophagus until the tip protrudes on the gastric pouch. (Figures 29-32)

Figure 29. The anesthesiologist passes the OrVil™ device through the esophagus.

Figure 30. The anesthesiologist passes the OrVil™ device through the esophagus (continued).

Figure 31. The anesthesiologist passes the OrVil™ device through the esophagus (continued).

Figure 32. The anesthesiologist passes the Orvil™ device through the esophagus (continued).

The tip of the orogastric tube (Orvil™ 25mm device) attached to the anvil of the circular stapling device protrudes on the gastric pouch. (Figures 33, 34)

Figure 33. The tip of the Orvil™ protrudes on the gastric pouch.

Figure 34. The tip of the Orvil™ protrudes on the gastric pouch (continued).

The gastric pouch is opened with the hook. (Figure 35-37)

Figure 35. The gastric pouch is opened (continued).

Figure 36. The gastric pouch is opened (continued).

Figure 37. The gastric pouch is opened (continued).

The orogastric tube is grasped and passed through the gastrotomy. (Figures 38-42)

Figure 38. The orogastric tube is passed through the gastrotomy.

Figure 39. The orogastric tube is passed through the gastrotomy (continued).

Figure 40. The orogastric tube is passed through the gastrotomy (continued).

Figure 41. Exit of the OrVil device through the port in the left upper quadrant.

The orogastric tube is passed through the port in the left upper abdomen.

Figure 42. Exit of the OrVil device through the port in the left upper quadrant (continued).

The anesthesiologist places upwards the white piece of the anvil head towards the palate and pushes it through the oral cavity while the surgeon pulls the nasogastric tube. (Figures 43-44)

Figure 43. The anesthesiologist places upwards the white piece of the anvil head.

Figure 44. The anesthesiologist places upwards the white piece of the anvil head (continued).

With a Maryland dissector we fix the anvil. (Figures 45, 46)

Figure 45. The anvil is fixed.

Figure 46. The anvil is fixed (continued).

One leg of the anvil-retaining suture is cut in order to disconnect the anvil from the orogastric tube. (Figures 47-50)

Figure 47. The anvil-retaining suture is cut.

Figure 48. The anvil-retaining suture is cut (continued).

Figure 49. The anvil-retaining suture is cut (continued).

Figure 50. The anvil-retaining suture is cut (continued).

We usually secure the anvil with a suture in order to prevent any slippage into the gastric pouch.

The suture is held in place with a Crile forceps outside the trocar located in the right upper abdomen. (Figures 51-53)

Figure 51. The anvil is secured with a suture to prevent slippage into the gastric pouch.

Figure 52. The anvil is secured with a suture to prevent slippage into the gastric pouch (continued).

Figure 53. The anvil is secured with a suture to prevent slippage into the gastric pouch (continued).

d) Preparation of the Alimentary Limb

Once the anvil is properly placed, the reverse Trendelenburg position will be changed to a neutral position and the alimentary limb is located. (Figure 54)

Figure 54. The alimentary limb is located.

The mesentery of the alimentary limb, is dissected with the vessel sealing device close to the stitch which attaches the greater gastric curvature to the small bowel. (Figure 55-57)

Figure 55. The mesentery of the alimentary limb is dissected.

Figure 56. The mesentery of the alimentary limb is dissected (continued).

Figure 57. The mesentery of the alimentary limb is dissected (continued).

Figure 58. Transection of the jejunum with linear stapling device.

Figure 59. Transection of the jejunum with linear stapling device (continued).

The jejunum is transected with a 60 mm gold cartridge of the linear stapling device, we usually flex the stapler, counterclockwise to obtain a slight oblique transection line, which further on will enable the introduction of the shaft of the circular stapling device. (Figures 58-61)

Figure 60. Transection of the jejunum with linear stapling device (continued).

Figure 61. Transection of the jejunum with linear stapling device (continued).

The blind side of the alimentary limb is opened, with the hook, near to the staple line. (Figures 62-64)

Figure 62. The blind side of the alimentary limb is opened.

Figure 63. The blind side of the alimentary limb is opened (continued).

Figure 64. The blind side of the alimentary limb is opened (continued).

The stitch to the greater curvature is cut. (Figure 65)

Figure 65. The stitch to the greater curvature is cut.

The mesentery of the jejunum is divided with the vessel sealing device, taking care not to injure the vascular supply of the alimentary or biliary limb. (Figures 66-70)

Figure 66. The mesentery of the jejunum is divided.

Figure 67. The mesentery of the jejunum is divided (continued).

Figure 68. The mesentery of the jejunum is divided (continued).

Figure 69. The mesentery of the jejunum is divided (continued).

Figure 70. The mesentery of the jejunum is divided (continued).

Before the circular anastomosis is performed we check that the alimentary limb reaches the gastric pouch without tension. (Figure 71)

Figure 71. We check that the alimentary limb reaches the gastric pouch without tension.

e) Gastrojejunal Anastomosis

Finally we create an end-to-side gastrojejunal circular anastomosis.

First of all, we enlarge the incision of the 12-mm port site in the left upper abdomen in order to introduce a plastic wound protector (Alexis®) that both protects and retracts the muscular wall facilitating the introduction of the circular stapling device EEA™ DST 25 XL 3,5. To introduce the stapler device through the muscular wall it is very useful to use the TAID®, a cone-shaped plastic device, that we remove once we have introduced the stapler in the abdominal cavity. (Figures 72-80)

Figure 72. Enlargement of the incision of the 12-mm port site in the left upper abdomen.

Figure 73. Enlargement of the incision of the 12-mm port site in the left upper abdomen (continued).

Figure 74. Plastic wound protector (Alexis®).

Figure 75. Introduction of the plastic wound protector (Alexis®).

Figure 76. Introduction of the circular stapler with the TAID®, a cone-shaped plastic device.

Figure 77. Introduction of the circular stapler with the TAID®, a cone-shaped plastic device (continued).

Figure 78. Introduction of the circular stapler with the TAID®, a cone-shaped plastic device (continued).

Figure 79. The TAID is removed once the stapler is introduced in the abdomen.

Figure 80. The TAID is removed once the stapler is introduced in the abdomen (continued).

The alimentary limb is anastomosed with the gastric pouch in an end-to-side fashion with the circular stapling device, as no tension is present. We normally secure the anvil with a suture to avoid any slipping into the gastric pouch. This suture is removed before firing the circular stapling device. (Figures 81-90)

Figure 81. The alimentary limb is anastomosed with the gastric pouch in an end-to-side fashion with the circular stapling device.

Figure 82. Introduction of the circular stapler through the open jejunum.

Figure 88. End-to-side anastomosis.

Figure 89. End-to-side anastomosis (continued).

Figure 90. Extraction of the stapler with the anvil adhered.

Once the circular anastomosis is completed, we introduce a 12-mm port through the Alexis. (Figure 91)

Figure 91. Once the anastomosis is finished, a 12-mm port is introduced through the Alexis.

Finally, the blind and open loop is resected with a 60mm cartridge of the Endo GIA™ linear stapler and extracted with an Endobag (Inzii universal specimen retrieval system, Applied Medical). (Figures 92-94)

Figure 92. The blind and open loop is resected.

Figure 93. The blind and open loop is resected (continued).

Figure 94. The resected specimen is removed inside a bag.

f) Testing the Anastomosis

Finally we check the integrity of the anastomosis performing an air leak test.

Patient is positioned in steep Trendelenburg position. The abdominal cavity is flushed with saline and the anesthesiologist introduces air in the gastric pouch through a nasogastric tube. (Figures 95-97). Surgical drains are not placed.

Figure 95. Air leak test.

Figure 96. Air leak test (continued).

Figure 97. Air leak test (continued).

To finish the surgery we remove the hepatic retractor and all the ports under direct vision.

Figure 98. The hepatic retractor and all the ports are removed under direct vision.

²Bariatric Surgery Unit, Hospital de Fuenlabrada, Madrid, Spain

ABSTRACT

Laparoscopic Roux-en-Y Gastric Bypass (RYGB) is considered the gold standard for the treatment of morbid obesity. However, there is no agreement on the technique that should be used for the gastrojejunal anastomosis (GJA; hand-sewn, linear mechanical, or circular mechanical). The choice of this type of technique may be influenced by the surgeon's preference and experience. It will also depend on the economic state of the institution where the bariatric surgeon works. Many studies have shown that there are no differences between techniques in terms of complications (anastomotic dehiscence, marginal ulcer, bleeding, stricture) or weight loss, whereas other studies observed significant differences between techniques. The aim of this chapter is to present the standard technique of the gastrojejunal hand-sewn anastomosis in RYGB.

Keywords: laparoscopic Roux-en-Y gastric bypass, hand-sewn anastomosis, surgical technique

INTRODUCTION

Bariatric surgery is considered the most effective treatment for morbid obesity, resulting in significant weight loss, as well as improvement of associated comorbidities [1]. Considering surgical techniques, Roux-en-Y gastric bypass (RYGB) is the gold standard

procedure for many surgeons. Actually, it is the second most-frequently performed technique, but in several countries, such as Spain, it is the most common bariatric procedure.

The technique used to perform the gastrojejunal anastomosis (GJA) varies among surgeons. This anastomosis is of vital importance, because the morbidity and the most severe complications of this surgery are associated with its correct performance, such as postoperative leakage (0-6.6%), marginal ulceration (0-8%) and stenosis (0-33%).

GJA can be performed using circular (CS) or linear mechanical staplers (LS), or completely hand-sewn (HS). Surgeons who propose each technique cite several specific advantages: a more consistent size of GJA with CS [2], an anastomosis less prone to stenosis with LS [3], while the HS technique reduces operative costs [4] but is considered more technically demanding [5].

INDICATIONS FOR RYGB

Indications for RYGB can be considered the following ones :

1. Primary weight loss procedure.
2. Ideal technique for metabolic syndrome patients.
3. Patients with esophageal reflux or Barret's disease.

PREOPERATIVE PREPARATION

The completion of the preoperative protocol prior to bariatric surgery requires the participation of several specialties, such as surgeons, endocrinologists, dietitians, gastroenterologists, anesthesiologists, pulmonologists and psychiatrists, who combine a medical, nutritional and endocrinological work-up to evaluate possible surgical candidates. The preoperative assessment included abdominal ultrasound, barium swallowing, upper gastrointestinal endoscopy, analytical determination of nutritional parameters and polysomnography.

SURGICAL TECHNIQUE

Instrumentation

At our institution we used the following surgical material for this technique:

1. Two 12 mm, one 11 mm and one 5 mm ports
2. Liver retractor
3. 30° scope
4. Harmonic scalpel (Harmonic ACE; Johnson & Johnson)
5. Veress needle
6. Three atraumatic graspers (one of the long size)

7. Suction-irrigator
8. Absorbable suture 3/0 monofilament
9. Echelon 45 mm (blue and white cartridges) (Johnson & Johnson, USA)
10. Gauzes
11. Clip applicator (optional)

PATIENT, PORT AND SURGEON POSITIONS

a) Patient Position

Patients are placed on an operating table in supine position with closed legs and only the left arm opened. Intermittent pneumatic compression devices are used to help to prevent venous thromboembolisms. The legs and hips are secured with safety straps to the operating table. An orogastric tube of 36 Fr is placed into the stomach in order to calibrate the gastric pouch during stapling and transection (Figure 1).

b) Port Position

Pneumoperitoneum to a pressure of 12-14 mmHg is achieved through Veress needle technique at Palmer point in the left upper quadrant. A first 11-mm port is inserted at the junction of the upper two thirds and lower one third of the line joining the xiphoides to the umbilicus, slightly bleached to the left of the patient. This is the camera port.

Figure 1. Patient position.

Two 12-mm working ports are inserted in the left and right hypochondrium areas in the midclavicular line, the port for left hand slightly more cranially than the port for right hand. A 5-mm port is inserted in the epigastrium. A liver retractor is used to retract the left lobe of the liver.

Another 5-mm port is placed on the left side in anterior axillary line at the level of the umbilicus. This is used by the first assistant, located on the left side of the patient. This is used mainly to retract the stomach or to help in the small bowel mobilization (Figure 2).

c) Surgeon Position

The operating surgeon stands on the right of the patient. The first assistant surgeon stands on the left side of the patient. The camera (second assistant) is on the right side of the operating surgeon. The scrub nurse is beside the first assistant.

Monitor is placed on the upper part of the patient for assistant and surgeon view (Figure 3).

Figure 2. Ports position.

Figure 3. Surgeon position.

Figure 4. Identification of the angle of Treitz.

PROCEDURE

a) Identification of Angle of Treitz

The procedure begins identifying the angle of Treitz, in the mesentery of the transverse colon (Figure 4). Once the initial part of the jejunum is identified in the angle of Treitz, 60 cm are counted distally. At that point the intestinal section is performed with a white cartridge on the mechanical stapler (Figures 5, 6). The mesentery of the small intestine is also sectioned at this level, allowing the distal stump to reach the gastric pouch without tension (Figures 7, 8).

b) Alimentary Limb Count

From the distal stump of the sectioned jejunum, 150 cm of jejunum is counted distally. It is at that point where the jejununo-jejunal anastomosis will be performed (Figure 9).

Figure 5. 60 cm of jejunum are measured distally.

Figure 6. 60 cm distal from the angle of Treitz the bowel is sectioned.

Figure 7. The mesentery of the small intestine is also sectioned at this level.

Figure 8. The mesentery of the small intestine is also sectioned at this level (continued).

Figure 9. From the distal stump of the sectioned jejunum, 150 cm of jejunum is measured distally.

Figure 10. A fixation suture is performed between the biliary limb and the alimentary limb.

c) Jeyuno-Jejunal Anastomosis (JJA)

Once the length of the alimentary limb is counted, a fixation suture is performed between the biliary limb and the alimentary limb (Figures 10, 11). Then an orifice is opened with the harmonic scalpel very close to the suture, until reaching the lumen of both limbs (Figures 12, 13). A jaw of the stapler is inserted into each hole (Figure 14). It is important to check the posterior face of the future jejunum and anastomosis so that it is well aligned, to avoid stapling the mesentery (Figure 15). Carefully the stapler is removed of the JJA. Close attention must be paid to confirm that the stapling line is correctly performed and without signs of bleeding (Figure 16).

Figure 11. A fixation suture is performed between the biliary limb and the alimentary limb (continued).

Figure 12. Enterotomies in both bowel limbs.

Figure 13. Enterotomies in both bowel limbs (continued).

Figure 14. A jaw of the stapler is inserted into each hole.

Figure 15. Mechanical anastomosis with linear stapler.

Figure 16. Inspection of anastomosis after removal of the stapler.

Figure 17. Running suture to close the enterotomies after the jejunum-jejunum anastomosis

Then a running suture is performed to close the orifice, finishing the jejunum-jejunum anastomosis (Figure 17- 19). The closure of the mesenteric defect is optional, and it can be made with a non-reabsorbable suture (Figure 20).

d) Bipartition of the Omentum

To reduce the tension when lifting the alimentary limb for the anastomosis with the gastric pouch, it is convenient to split the omentum in half with the harmonic scalpel (Figure 21).

Figure 18. Running suture to close the enterotomies after the jejunum-jejunum anastomosis

Figure 19. Running suture to close the enterotomies after the jejunio-jejunal anastomosis (continued).

Figure 20. Optional closure of the mesenteric defect.

Figure 21. Split of the omentum.

Figure 22. Identification of the angle of His.

e) Identification of Angle of His

The dissection begins identifying the angle of His, taking down the fat patch at the upper part of the fundus. An important trick is to visualize the left crura of the diaphragm. Once the crura is identified, a gauze is placed between the fundus and spleen. The mobilization of the fat patch provides an adequate exposure of this area for optimal stapling and transecting of the stomach. Any hiatal hernias should be addressed at this time and repaired in a posterior fashion (Figures 22, 23).

Figure 23. Identification of the left crura.

Figure 24. Opening of a window in the lesser curvature.

f) Creation of the Gastric Pouch

Using the harmonic device, a window must be opened in the lesser curvature of the stomach 5-6 cm distal to the esofagogastric junction (Figures 24, 25). Retrogastric adhesions must be freed in order to get into the epiploic transcavity (Figure 26). Once getting into the transcavity a horizontally stapling is performed (Figures 27, 28). Then the rest of the retrogastric adhesion must be divided (Figure 29), in order to remove adhesions or fat from the area where the GJA is going to be performed.

Figure 25. Opening of a window in the lesser curvature (continued).

Figure 26. Attempt to enter into the omental transcavity.

Figure 27. Once entered the transcavity, a horizontal stapling is performed.

Figure 28. Once entered the transcavity, a horizontal stapling is performed (continued).

Figure 29. Division of retrogastric adhesions.

Figure 30. Goldfinger is a helpful tool that can dissect easily the posterior adhesions of the stomach.

Figure 31. Goldfinger is a helpful tool that can dissect easily the posterior adhesions of the stomach (continued).

Figure 32. Insertion of the calibration bougie.

The Goldfinger is a helpful tool that can dissect easily the posterior adhesions of the stomach. The second assistant is the one who has to manipulate the instrument and must be extremely aware because of a probable lesion of the spleen (Figures 30, 31).

Once the dissection is completed, a 36-French blunt-tipped bougie tube is slowly advanced under direct visualization (Figure 32). The pouch is confectioned with 2-3 blue cartridges cranially directed to the angle of His (Figure 33). The Goldfinger is retracted to the left of the patient before firing the stapler in order to avoid leaving too much posterior wall of the gastric pouch (Figure 34).

Figure 33. Confection of the pouch with linear stapler.

Figure 34. The movement of the Goldfinger to the left prevents from leaving excessive posterior wall of the pouch.

Once finishing the procedure of the gastric pouch, the alimentary limb must be lifted cranially, avoiding a twist of the bowel (Figure 35).

g) Performing the Gastro-Jejunal Anastomosis

A running absorbable monofilament suture 3/0 is made approaching the posterior wall of the alimentary limb and the horizontal staple line of the gastric pouch (Figures 36, 37). After performing the posterior layer of suture, 2 orifices are made in the gastric pouch and the alimentary limb, trying to be conservative with the size of the orifices and that these holes are symmetrically facing in order to avoid twists in the anastomosis (Figures 38-41).

Figure 35. The alimentary limb is lifted cranially.

Figure 36. A running suture is made approaching the posterior wall of the alimentary limb and the horizontal staple line of the gastric pouch.

Figure 37. A running suture is made approaching the posterior wall of the alimentary limb and the horizontal staple line of the gastric pouch (continued).

Figure 38. Orifice in the gastric pouch.

Figure 39. Orifice in the gastric pouch (continued).

Figure 40. Orifice in the gastric pouch (continued).

Figure 41. Orifice in the alimentary limb.

Figure 42. Suture of the second posterior layer of the anastomosis.

The suture of the second posterior layer of the anastomosis begins with a 3/0 re-absorbable suture from lateral to medial direction, avoiding unsutured areas, especially in the vertices. This second posterior suture must include all the layers (serosa, muscular, submucosa and mucosa) (Figures 42-44).

The orogastric tube is then progressed through the future anastomosis through both orifices inside the alimentary limb lumen, to calibrate the final diameter (Figure 45). Subsequently, the suture of the first anterior layer of the anastomosis begins, also in latero-medial direction with 3/0 reabsorbable monofilament material (Figures 46, 47). Finally, it is optional to make a second suture layer on the anterior face with the same suture material (Figure 48).

Figure 43. Suture of the second posterior layer of the anastomosis. Transmurular and in medial to lateral direction.

Figure 44. Suture of the second posterior layer of the anastomosis. Transmurular and in medial to lateral direction (continued).

Figure 45. The bougie is progressed through the anastomosis.

Figure 46. Suture of the first anterior layer of the anastomosis over the bougie.

Figure 47. Suture from lateral to medial direction.

Figure 48. Second anterior layer suture is optional.

h) Checking the Staple Line and Anastomosis Integrity

Once all the procedure is created, intraluminal bleeding in the staple line must be discarded. If bleeding is observed, haemostasia with clips should be performed.

Finally, a methylene blue dye test is performed, excluding any spillage of blue contents into the peritoneal cavity. The orogastric tube is removed after having performed the tightness test.

Surgical drains are not necessary unless there is high concern for bleeding or leak postoperatively.

ABSTRACT

Nowadays, laparoscopic Mini-Gastric Bypass (MGB) has become a popular bariatric surgery procedure. MGB is becoming more and more popular as shown by the numerous articles published over the past 15 years, supporting the operation as a short and simple procedure with excellent outcomes and low complication rates. Although this technique seems to be very simple, there is still confusion amongst surgeons. Therefore some important surgical details are essential in order to prevent potential severe complications after surgery. The aim of the chapter is to describe and show our standardize technique basing on different surgical pictures.

Keywords: mini-gastric bypass, surgical procedure

INTRODUCTION

The Laparoscopic Mini-Gastric Bypass (MGB) has become a popular bariatric surgery procedure. Its frequency of performance has increased considerably in the current decade and now is being done as a routine procedure in most countries around the world [1, 2]. MGB was designed to overcome the limitations of RYGB and improve its outcomes. MGB constructs a lesser curvature gastric conduit to or below the “crow’s foot” and an anastomosis to an anti-colic loop of jejunum 150-200 cm distal to the Trietz ligament (Figure 1). The MGB was first

* Patricia Sanchez Salcedo, RN.

performed by Rutledge in 1997 [3] in the era of open bariatric surgery and at the dawn of the era of Minimally Invasive Surgery (MIS). The operation is based on sound general surgical principles combining a “non-obstructive” Collis Gastroplasty, which is an esophageal lengthening procedure with a Billroth II ante-colic Loop gastro-jejunostomy. As the medically accurate name (Collis Gastroplasty with Antecolic Billroth II Loop gastro-jejunostomy) was a bit much; and as it was the dawn of the era of MIS, the simple application of these two routine general surgical procedures was named “Mini” Gastric Bypass.

MGB has important technical details like the pouch size, gastro-jejunostomy size and bypass length. When these individual components of the operation are used in different ways, these give different results. There are reports of bypass being used from 150 cm to up to more than 300 cm. MGB gives different results as per the length of the bypass. In addition to this, different surgeons are performing gastrojejunostomy in different ways with different staples varying from 30 mm to 60 mm staple sizes and hand sewn instead of total stapled anastomosis.

Various reports have been published from different parts of the world to document this procedure giving sustained and long-term weight loss comparable to or even better than the classical Roux-en-Y gastric bypass [4]. MGB has only one anastomosis which makes it easy to perform, revise or reverse [5]. There is a growing number of publications supporting this operation to be a short and straightforward procedure with low complication rates and excellent outcomes [6, 7].

MGB addresses many perceived limitations of other procedures and offers many features of an ideal bariatric surgery. It has now been shown in many short- and long-term studies, as well as in many controlled prospective randomized trials, to result in excellent weight loss, good resolution of associated medical illness and very high levels of patient satisfaction [8].

Figure 1. MGB. A vertical channel starting below the crow's foot is stapler-divided proximally going to the left of the angle of His; the long gastric pouch is anastomosed by a wide antecolic gastro-jejunostomy ~200 cm distal to Treitz ligament.

The mechanism of action and the power of MGB is complex and cannot be completely covered here in this technique focused monograph. Suffice to say that a patient survey on over 3,000 of Dr. Rutledge's MGB patients demonstrated a unique non-obstructive restrictive component and a minimal malabsorptive component along with significant fatty food intolerance. Additionally, MGB produces hormonal changes and also affects patient's bile acid pool [9]. Numerous general surgery and bariatric studies show that operations which includes both a gastric and an intestinal component outperforms purely gastric restrictive procedures, like the Gastric Band and Sleeve Gastrectomy [10, 11].

After Rutledge's work, in 2002 Carbajo et al. in Spain (after having performed the RYGB for > 10 years) initiated the OAGB variant of the MGB (the BAGUA—*Bypass Gastrico de Una Anastomosis*) to prevent potential gastroesophageal (GE) reflux [12]. However, after the MGB with its low pressure tube [13], GE reflux has occurred in < 1% and cancer is almost unknown. The MGB and OAGB are followed by superior resolution of co-morbidities, good quality of life, and usual lasting weight loss.

SPECIFIC CONTRAINDICATIONS FOR MGB

1. primary short gut (total small intestine length < 350 cm) or secondary short bowel syndrome (after intestinal resections)
2. Crohn's disease

PREOPERATIVE PREPARATION

The preoperative work-up for bariatric surgery is performed by a multidisciplinary team, including surgeons, endocrinologists, dietitians, gastroenterologists, anesthesiologists and psychiatrists, who combine a medical, nutritional, and endocrinology workup to evaluate potential surgical candidates. The patient follows a strict pre-operative very low-calorie diet (VLCD) as prescribed by our registered nutritionist, preferably for 15 days. The patient follows incentive spirometry exercises and, if need be, pre-operative chest physiotherapy and CPAP/BIPAP non-invasive ventilation.

Anesthesia

An enhanced recovery after surgery (ERAS) programme is followed with an opioid-free anesthesia. Central vein and bladder catheters were not used.

SURGICAL TECHNIQUE

Instrumentation

1. Three 12 mm and one 5 mm ports

2. Nathanson liver retractor
3. 30° scope
4. Harmonic scalpel (Harmonic ACE; Johnson & Johnson)
5. Veress needle
6. Three atraumatic graspers (one of the long size)
7. Suction irrigator
8. Echelon 60 mm (gold and blue cartridges) (Johnson & Johnson)
9. Peristrip-dry
10. Gauzes
11. Clip applicator (optional)

PATIENT, PORT AND SURGEON POSITIONS

a) Positioning of the Patient

The operation is performed with the patient in the supine position with legs open and with 45 degrees inclined position. The attachment of the patient to the surgical table is made by placing two belts (on the abdominal area and below the level of the thighs, respectively). The prevention of thrombotic events is made with use of graduated compression stockings and intermittent pneumatic boots. Urinary bladder catheterization is not used (Figure 2).

Figure 2. Patient initial position.

b) Surgeons Position

The surgeon stands between the legs, with the 1st assistant, who handles the camera and the auxiliary clamp, and the scrub on the right. Monitor is placed on the upper part of the patient for assistant and surgeon view (Figure 3).

Figure 3. Surgeon position.

c) Pneumoperitonium and Placement of the Ports

The pneumoperitoneum is performed by means of a direct puncture with a Veress needle in the left upper quadrant, near the costal margin at the level of the midclavicular line (Palmer's point). The initial pressure is set at 15 mmHg and maintained till the expected pressure (about 15 mmHg) is reached.

Figure 4. Usual location of ports for the MGB.

The surgery initiates by the placement of the 12 mm permanent trocars for introduction of 30 degrees optics/camera placed at the mesogastrium between 12-15 cm below the xiphoid process and 3 cm to the left of the midline, considered as number 1 trocar. The trocar number 2 of 12 mm is inserted in the epigastrium and then is replaced by a Nathanson liver retractor (LR) that is used to retract the left lobe of the liver. The number 3, disposable of 12 mm, is used by the surgeon's left hand, placed on the right side of the patient in an intermediate position between the previous two, 3-5 cm lateral to the midline. The number 4, also permanent of 5 mm, is placed along the left costal margin in the anterior axillary line to the 1st assistant. The last trocar, number 5, disposable of 12 mm, is placed adjacent to the left costal margin in the hemi-clavicular line to surgeon's right-hand manipulation. The pneumoperitoneum is maintained by trocar number 5 (Figure 4).

PROCEDURE

The operation begins with the dissection of the esophagogastric angle and the opening of the left gastrophrenic ligament with a harmonic scalpel, so as to expose the lateral aspect of the left diaphragmatic crus. Then, the resection of the fat pad of the esophagogastric junction (Belsey's fat) is performed. Then, the surgeon proceeds to open the lesser omentum between the crow's foot (junction of body and antrum of the stomach) and pylorus, next to the insertion of the Latarjet nerve, using a harmonic scalpel until the exposure of the posterior gastric wall (Figures 5-13).

Figure 11. Dissection of retrogastric adhesions.

Figure 12. Entrance to the omental transcavity.

Figure 13. Division of retrogastric adhesions.

The gastric pouch must be lengthy and narrow, measuring around 15-18 cm, with a 50-150 ml reservoir capacity. The pouch is created using 01 unit of 60 mm blue cartridges to perform the horizontal section. A gastric calibration tube should be engaged along the lesser curvature of the stomach to guide the vertical section, which will be carry on thanks to 02 to 03 stapler units (Figures 14-21).

Figure 14. The gastric pouch is measured.

Figure 15. 15cm distally to the hiatus, a horizontal stapling is performed.

Figure 19. Confection of the pouch with vertical staplings (continued).

Figure 20. Confection of the pouch with vertical staplings (continued).

Figure 21. Complete separation of the pouch from the gastric remnant.

The Treitz ligament is then identified and the small bowel is counted until 200 cm from the Treitz angle, determining the exclusion of part of the stomach, duodenum, and proximal jejunum from the food pathway. This segment is then attached to the pouch previous section of greater omentum. A vertical or slightly oblique omega-loop, isoperistaltic, antecolic, and side-to-side 25mm-gastrojejunostomy is performed using a 45mm white cartridge; the orifice for the cartridge insertion is closed by means of a continuous suture with 3-0 polydioxanone (Figures 22-33).

Figure 31. Closure of the remaining holes with running suture (lateral to medial).

Figure 32. Closure of the remaining holes with running suture.

Figure 33. Finished gastroenteral anastomosis.

Finally, in order to avoid the excess of tension, a stitch between the gastric remnant and the proximal jejunum is performed. Surgical drains are not necessary unless there is high concern for bleeding or leak postoperatively (Figures 34-36).

Figure 34. Stitch between the gastric remnant and the proximal jejunum is performed to reduce tension in anastomosis and prevent from twisting.

Figure 35. Stitch between the gastric remnant and the proximal jejunum is performed to reduce tension in anastomosis and prevent from twisting (continued).

Figure 36. Stitch between the gastric remnant and the proximal jejunum is performed to reduce tension in anastomosis and prevent from twisting (continued).

PRECAUTIONS TO BE TAKEN

1. The gastric pouch should be long and wide.
2. The Initial point of antral division on the lesser curvature of the stomach should be distal to crow's foot, so as to maintain the vascularity of the tip of the gastric pouch, preserving the blood supply arising from the lesser curvature of the stomach, as well as avoiding GE reflux.
 - a Adequate channel of the bypassed stomach has to be maintained for the drainage of secreted fluid.
 - b Care must be taken to avoid twist in the gastric pouch
 - c Perfect hemostasis has to be attained. Energy sources should never be used to achieve hemostasis on the staple-line area.
 - d Gastro-jejunostomy should never be less than 25 mm in diameter, maintaining proper alignment of the anastomosis and avoiding twist in the same.

ABSTRACT

Laparoscopic One-Anastomosis Gastric Bypass (OAGB) is actually the third most-frequent bariatric approach. It has shown an exponential growth during the last decade, based on its easy technique and excellent mid- and long-term results. OAGB-BAGUA appeared as a modification of the Mini-gastric bypass (MGB), aiming to reduce the biliary reflux and measuring the total bowel length, to reduce the risk of malnutrition secondary to an unknown short bowel.

Actually, the IFSO position statement about OAGB established that all the procedures with a single gastro-entero anastomosis must be named as OAGB. Thus, under this acronym are now included MGB, Single-anastomosis gastric bypass, Omega-loop gastric bypass and OAGB-BAGUA. However, the OAGB-BAGUA has a significant difference to the others; it is the only one in which the total bowel length is measured, whereas in the others only the biliopancreatic or the common limb lengths are determined.

Keywords: laparoscopic one-anastomosis bypass, OAGB, BAGUA, surgical technique

INTRODUCTION

One-Anastomosis gastric bypass (OAGB-BAGUA) appeared as a modification of the original Mini-Gastric Bypass (MGB). Carbajo developed in 2002 the OAGB-BAGUA aiming to reduce the most frequent complications of MGB (biliary reflux and malnutrition), but preserving the advantages of a single-anastomosis gastroenterostomy. The most important differences between OAGB-BAGUA and MGB are a longer gastric pouch, a calibrated gastroenteroanastomosis at 2.5 cm of diameter (in comparison with 5 cm-wide anastomosis in OAGB), a latero-lateral running suture between the gastric pouch and the biliopancreatic limb (BPL) and the measurement of the total bowel length.

The length of the gastric pouch in OAGB-BAGUA is between 18-20 cm, whereas in the MGB it is around 15cm. The longer the pouch, the lower the risk of biliary reflux reaching the esophagus. The calibration of the anastomosis aims to reduce the biliary reflux from the bowel to the gastric pouch. Moreover, it also reduced the risk of developing Dumping syndrome as it slows the pass of the alimentary bolus to the bowel and consequently reduces the appearance of hormonal peaks. The latero-lateral running suture aims to position the BPL laterally to the gastric pouch, facilitating the pass of its content to the postanastomotic common limb (CL) rather than entering into the gastric pouch. Moreover, it may also reduce the tension on the anastomosis [1-3].

Finally, the measurement of the total bowel length (TBL) is considered by us as a safety issue. The TBL is not a constant among different subjects, ranging between 300 and 800 cm [4]. If we try to establish a technique with constant BPL (like the MGB) or constant CL (like the SAGI), the outcomes will be completely different between patients. If we establish a standard 150-200 cm of BPL like in the MGB and the patient has a TBL of 800 cm, the technique will be useless as bariatric approach with a minimal effect on weight loss and probably also on remission of comorbidities. On the other hand, if the patient presents a TBL of 350 cm, he will probably develop a severe malnutrition. Thus, we advocate for measuring the total bowel length and establishing the BPL and CL according to a percentage of TBL. A very aggressive approach, leaving a BPL of 60% of the TBP and a CL of 40% of TBL, with a minimal CL of 200 cm, was initially supported. With this approach mean BMI of 25.1 Kg/m² and remission rates of type 2 diabetes (T2D), hypertension and dyslipidemia over 90% after 5 years were obtained. Despite the prevalence of protein malnutrition being very low (0.33%) and there was no need for revisional surgery for this reason, the prevalence of diverse vitamin and mineral deficiencies (iron, vitamin D, vitamin B12,...) was high. Most of these carencies can be satisfactorily managed with oral supplementation. Notwithstanding, we actually may recommend a more conservative approach with a BPL/CL ratio of 50%:50%, leaving at least 250 cm. Our results support that with this ratio, mean BMI was 25.8 Kg/m² and remission of comorbidities was very similar to the more aggressive technique, but the supplementation needs were significantly lower [5, 6].

Actually, the IFSO position statement about OAGB [7] established that all the procedures with a single gastro-entero anastomosis must be named as OAGB. Thus, under this acronym are now included MGB, Single-anastomosis gastric bypass, Omega-loop gastric bypass and OAGB-BAGUA. However, these techniques present significant differences between them. Some of them measure the BPL, others the CL [8]. The length of the gastric pouch and the size of the anastomosis are also different. OAGB-BAGUA is the only technique in which the total bowel length is measured.

INDICATIONS FOR OAGB

Indications for OAGB-BAGUA can be considered the following ones:

1. Primary weight loss procedure.
2. Ideal technique for metabolic syndrome patients.
3. Revisional surgery after failure of restrictive procedures

CONTRAINDICATIONS FOR OAGB

1. Total bowel length <350 cm
2. Patients without possibility of follow-up: As in all malabsorptive procedures, a close follow-up is mandatory to rule out nutritional deficiencies and to supplement it accordingly.
3. Inflammatory bowel disease

Relative contraindications can be considered as follows:

1. Active tobacco habit: Increases the risk of anastomotic ulcers
2. Chronic medication intake: The absorption of this drugs cannot be predicted or it can be anarchic
3. Presence of gastroesophageal reflux disease (GERD): Despite several authors defend that OAGB is an excellent therapeutic option for obese patients with GERD, we are a little bit more sceptical with this affirmation. GERD is caused by an incompetent inferior esophageal sphincter, allowing the pass of gastric acid to the esophagus. Despite in OAGB with hiatal hernia the diaphragmatic crus are closed, the sphincter probably still remains incompetent. Thus, it may allow the pass of biliary reflux to the esophagus. In patients with GERD we would rather prefer to perform a Roux-en-Y gastric bypass.

PREOPERATIVE PREPARATION

A multidisciplinary team performed a combined medical, nutritional, and endocrinological work-up to evaluate potential surgical candidates. Preoperative assessment included an analytical evaluation of their metabolic and nutritional status as well as abdominal ultrasound and upper gastrointestinal series. Psychologists undertook additional interviews to evaluate patient's commitment in following guidelines and a strict diet in the postoperative course. A weight loss of at least 10% of the patient's weight was considered an indispensable preoperative condition to undergo the bariatric approach. Therefore, a dietician established a low-calorie diet according to individual needs of each patient and nutritional hypocaloric hyperproteic formulas as their sole nutrition during 2 weeks before surgery. Patients received clear information about potential perioperative complications, as well as precise postoperative guidelines, required nutritional supplementation, and inherent consequences of not following them.

SURGICAL TECHNIQUE

Instrumentation

The following surgical material is necessary to perform this technique:

1. Two 12 mm, one 11 mm and three 5 mm ports
2. Liver retractor
3. 30° scope
4. Harmonic scalpel
5. Veress needle
6. Three atraumatic graspers
7. Suction-irrigator
8. Needle-gripper
9. Absorbable suture 2/0 monofilament (barbed sutures if available)
10. Endostapler (5-6 cartridges)
11. Gauzes
12. Rubber band
13. Clip applicator (optional)

PATIENT, PORT AND SURGEON POSITIONS

a) Patient Position

Patients are placed on an operating table in supine position with open legs and both arms adhered to the trunk. The legs and hips are secured with safety straps to the operating table. Monitor is placed on the upper part of the patient for assistants and surgeon view (Figure 1).

Patient position

Figure 1. Patient position.

b) Port Position

Pneumoperitoneum to a pressure of 12-14 mmHg is achieved through Veress needle technique at Palmer point. A first 12-mm optical port is inserted at the left flank in the midclavicular line under direct vision. A 10-mm supraumbilical port is placed 15 cm caudal to the xiphoid apophysis slightly bleached to the left of the patient, avoiding inserting it in the line alba. A second 12-mm port is inserted at the right flank in the right midclavicular line. Two 5-mm ports are placed at right and left hypochondria in the anterior axillary lines. Finally, a third 5-mm port is inserted in right iliac fossa (Figures 2 and 3).

Figure 2. Ports position scheme.

Figure 3. Ports position.

c) Surgeon Position

We initiate our procedure with small bowel measurement from angle of Treitz to ileocecal valve and record TBL. The operating surgeon stands on the right of the patient. The

first assistant surgeon stands between the legs and the camera (second assistant) is on the left side of the operating surgeon (Figure 4).

Figure 4. Surgeon position.

Figure 5. Lifting of the greater omentum.

PROCEDURE

a) Bowel Length Measurement

The procedure begins lifting the greater omentum (Figure 5) and identifying the angle of Treitz, in the mesenterium of the transverse colon (Figure 6). The TBL is determined measuring distally from the angle of Treitz angle to the ileocecal valve (Figure 7).

Figure 6. Identification of the angle of Treitz.

Figure 7. Small bowel measurement.

Figure 8. Temporary landmark in the mesentery at 250 cm of the angle of Treitz.

Figure 9. Measurement of the total bowel length up to the ileocecal valve.

Figure 10. Silicon handle is introduced.

Given that the mean TBL in our patients is around 500 cm, a landmark is temporarily placed at 250 cm from the angle of Treitz, gripping the mesenterium with a grasper (Figure 8).

To continue with further counting of the small bowel up to the ileocecal valve, the patients are moved to Trendelenburg's position (Figure 9).

After having determined the TBL, the site for the anastomosis is decided at a rate of BPL/CL of 50%/50%. A silicon handle is introduced into the abdomen and placed in the decided site for anastomosis (Figure 10). A hole is performed in the mesenterium to introduce the handle, gripping it with a grasper for future elevation of the bowel at the time of performing the anastomosis (Figures 11 and 12).

The correct and tension-free approximation of the selected bowel limb to the incisura angularis of the stomach is corroborated, lifting from the handle cranially (Figure 13).

In case of several tension, the greater omentum is divided to reduce the distance between bowel limb and stomach (Figure 14).

Figure 11. A hole is performed in the mesenterium to introduce the handle.

Figure 12. The silicon handle is introduced through the hole in the mesentery.

Figure 13. Approximation of the selected bowel limb to the incisura angularis.

Figure 14. Division of the greater omentum.

b) Dissection of Angle of Hiss

After having finished the TBL measurement, the surgeon moves between the legs, the camera assistant reminds on the right side of the patient and the first assistant moves to the left side of the patient. The operating table is now moved to anti-Trendelenburg position (Figure 15). The left lobe of the liver must be retracted using a liver retractor inserted through the 5 mm port placed in right hypochondrium.

Patient position

Figure 15. Position of the surgical team for the confection of the gastric pouch and anastomosis.

For the dissection of the angle of Hiss, the first assistant grips the fundus of the stomach with a grasper and pulls it to the left of the patient and downwards (Figure 16). The dissection begins identifying the angle of Hiss, dividing the phreonoesophageal and phrenogastric membranes until obtaining a visualization of the left crura (Figures 17 and 18).

c) Division of the Lesser Omentum

The hepato-gastric ligament is divided from the incisura angularis cranially until visualizing the right diaphragmatic crura (Figure 19). It is important to preserve the hepatic branch of the vagus traversing the lesser omentum, as this nerve has important metabolic effects (Figure 20).

Figure 16. Exposure of the angle of Hiss.

Figure 17. Division of the phrenoesophageal and phrenogastric membranes.

Figure 18. Identification of the left crura.

Figure 19. The hepato-gastric ligament is divided from the incisura angularis cranially.

Figure 20. Preservation of the hepatic branch of the vagus.

Once finished the division of the lesser omentum, the anterior part of the phrenoesophageal membrane is divided, in order to allow a better descense of the gastric pouch at the time of performing the anastomosis (Figure 21).

d) Retrogastric Window and Pouch Conformation

The retrogastric window is opened at the level of the inferior branch of the crow's foot (Figure 22). The first assistant pulls from the antrum downwards and the surgeon divides the fat in the lesser curvature until opening a window in the retroperitoneal cavity (Figures 23 and 24).

The stapler is introduced through this retrogastric window and a first cartridge is used to perform the horizontal division of the stomach. The surgeon introduces the stapler with his left hand through the 12-mm port on the right side of the patient. The right hand of the surgeon lifts the stomach upwards in order to descend 1-2 cm the place of division, consequently obtaining a longer pouch (Figure 25).

Figure 21. Division of the anterior part of the phrenoesophageal membrane.

Figure 22. The retrogastric window is opened at the level of the inferior branch of the crow's foot.

Figure 23. The first assistant pulls from the antrum downwards.

Figure 24. The fat in the lesser curvature is divided until opening a window in the retroperitoneal cavity.

Figure 25. The stapler is introduced through the retrogastric window in the lesser curvature and a first cartridge is used to perform the horizontal division of the stomach.

Then, the surgeon introduces the stapler with his right hand through the 12-mm port on the left side of the patient. The stapler is closed without firing and serves as helpful tool for the correct position of the calibration bougie (Figures 26 and 27). The confection of the pouch is performed with vertical division of the stomach cranially, adjusted to the calibration bougie.

Figure 26. Vertical positioning of the stapler, helping the introduction of the calibration bougie.

Figure 27. Introduction of the calibration bougie.

Three or four cartridges are necessary for the complete transection of the stomach (Figure 28). After the first vertical stapling, the retrogastric fat is divided cranially until reaching an opening window in the angle of Hiss (Figure 29 and 30). The last stapling is performed through the window opened in the angle of Hiss and thereby the section of the stomach is completed (Figures 31 and 32).

Figure 28. Vertical stapling to construct the gastric pouch.

Figure 29. Division of the retrogastric fat.

Figure 30. Window in the angle of Hiss, adjacent to the left diaphragmatic crura.

Figure 31. The last stapling is performed through the window opened in the angle of Hiss.

Figure 32. The section of the stomach is completed.

Figure 33. The BP limb is pulled up cranially through the silicon handle.

Figure 34. The running suture begins 8-10 cm cranially from the horizontal staple line (in the middle of the 2nd vertical stapling).

e) Latero-Lateral Gastroenteral Running Suture

Once the confection of the gastric pouch is finished, the next step is the performance of the latero-lateral running suture to attach the BP limb to the lateral face of the gastric pouch. The BP limb is pulled up cranially through the silicon handle (Figure 33). The running suture begins 8-10 cm cranially from the horizontal staple line (Figures 34-36) and continues until to the horizontal staple line (Figures 37-40).

Figure 35. The running suture begins 8-10 cm cranially from the horizontal staple line (in the middle of the 2nd vertical stapling) (continued).

Figure 53. The suture is performed from distal to proximal, performing the first stitch on the bowel and the second on the pouch (continued).

Figure 54. The barbed suture does not require a knot at the end of the suture.

Figure 55. The bowel is clamped proximally and distally to the anastomosis and methylene blue dye is applied through the calibration bougie, in order to rule out anastomotic leaks.

The bowel is clamped proximally and distally to the anastomosis and methylene blue dye is applied through the calibration bougie, in order to rule out anastomotic leaks (Figure 55). The orogastric tube is removed after having performed the tightness test.

Surgical drains are not necessary unless there is high concern for bleeding or leak postoperatively.

and Aniceto Baltasar, MD, PhD***

Hospital de Alcoy, Alicante, Spain

ABSTRACT

The duodenal switch procedure was described by DeMeester and colleagues in 1987 as a surgical solution for primary bile reflux gastritis or to decrease the postgastrectomy symptoms seen in patients after distal gastrectomy and gastroduodenostomy. Despite quite favorable outcomes reported in the literature, BPD-DS procedure has not been spread world-wide. One of the reasons for this is that the procedure is difficult to perform laparoscopically.

In this chapter we aim to describe the laparoscopic technique for duodenal switch.

Keywords: Duodenal switch; Laparoscopic technique

INTRODUCTION

The duodenal switch procedure was described by DeMeester and colleagues in 1987 as a surgical solution for primary bile reflux gastritis or to decrease the postgastrectomy symptoms seen in patients after distal gastrectomy and gastroduodenostomy [1]. In 1988, Hess and Marceau [2] adapted this procedure to the treatment of morbid obesity by adding a 75% longitudinal gastrectomy to reduce gastric capacity and acid production and extending the Roux limb to a length similar to that recommended by Scopinaro to induce fat malabsorption.

Michel Gagner [3] was the first to perform the DS by laparoscopy in September 1999 and Aniceto Baltasar [4] did so in May 2000.

The biliopancreatic diversion with duodenal switch (BPD-DS) combines a sleeve gastrectomy with a duodeno-ileal switch. This results in a restricted caloric intake and diversion of bile and pancreatic secretions to induce fat malabsorption.

Despite quite favorable outcomes reported in the literature, BPD-DS procedure has not been spread world-wide. There are 3 reasons for this. First, there is a perception that its malabsorptive component may be associated with metabolic complications, protein caloric malnutrition, or other nutritional deficiencies. Second, the procedure is longer and technically more demanding than other bariatric operations. Third, the procedure is difficult to perform laparoscopically.

INDICATION

1. As a primary weight loss procedure in patients with BMI >50 and metabolic syndrome.
2. As a second step in super obese (BMI > 50) and super super obese (BMI > 60) patients when maximum weight loss has reached the plateau, one year or one year and a half after the sleeve gastrectomy (SG).
3. In case of weight regain after SG.

PREOPERATIVE PREPARATION

Preoperative management of bariatric patients is performed by a multidisciplinary team that includes surgeons, endocrinologists, dieticians, anesthetists, physiotherapists, and psychiatrists, who combine medical, nutritional, and endocrine workup to evaluate potential surgical candidates.

Preoperative assessment includes abdominal ultrasound, biochemical evaluation of the nutritional status, respiratory physiotherapy and in selected cases polysomnography, upper GI contrast study and esophago-gastro-duodenoscopy.

All bariatric patients follow routine preoperative preparation including antibiotic and acid bronchoaspiration prophylaxis, and are admitted to hospital the afternoon before the surgery.

Anesthesia

Laparoscopic BPD-DS is performed under general anesthesia and endotracheal intubation. The patient is placed in French position with sequential compression stockings, and a special operating table fixation is used routinely.

SURGICAL TECHNIQUE

Instrumentation

1. One 12 mm (endopath), one 10 mm (camera trocar), and four 5 mm trocars
2. Nathanson liver retractor
3. 0° and 30° scope
4. Harmonic scalpel (Harmonic ACE; Johnson & Johnson)
5. Four atraumatic graspers
6. Laparoscopic needle holder
7. Suction irrigator device
8. Echelon 60 mm (gold and blue cartridges) (Johnson & Johnson)
9. Gauzes
10. Clip applicator (optional)
11. Sutures; 2/0 Polypropilene, 3/0 maxon, 2/0 silk

TROCARS AND SURGEONS POSITION

Six supraumbilical ports are routinely inserted. Long trocars are sometimes needed in patients who have a very thick abdominal wall. Usually a 12mm right subcostal trocar is inserted under direct vision four fingertips below the ribs, a 10mm supraumbilical trocar (camera) and four 5mm trocars on the left pararectal, right and left anterior axillary line and subxiphoid position (Figure 1).

Figure 1. Trocar position.

Figure 2. Surgeons' position.

Position of surgeons should vary depending on the step of the procedure. In the first part of the surgery (sleeve gastrectomy) the patient is placed in anti-Trendelenburg position and the surgeon stands between the patient's legs and the assistants stand laterally on the right and left side of the patient. Monitors are placed on the upper part at the head of the patient (Figure 2). Pneumoperitoneum is set to maximum pressure of 15 mmHg.

PROCEDURE

a) Sleeve Gastrectomy Step

We start with a 0 silk percutaneous traction of the round ligament to lift the liver. A Nathanson liver retractor is introduced through a 5mm subxiphoid port to retract the left lobe of the liver and to expose the anterior aspect of the stomach Figures 3-6.

Figure 3. Percutaneous traction of the round ligament to lift the liver.

Figure 4. Percutaneous traction of the round ligament to lift the liver (continued).

Figure 5. Percutaneous traction of the round ligament to lift the liver (continued).

Figure 6. Percutaneous traction of the round ligament to lift the liver (continued).

Figure 7. Assistants maintain a gentle traction between the greater curvature and the omentum.

Gastric resection begins by sealing the greater curvature vessels starting at the level of incisura angularis where it is easier to enter into the lesser sac. Once we get into the lesser sac we progress upwards with an ultrasonic dissector (Harmonic-ACE, Ethicon, US). In order to have the best view, assistants maintain a gentle traction between the greater curvature and the omentum.

It is very important to cut all adhesions between the pancreas and the posterior aspect of the stomach.

We continue the fundus liberation until the left crus and the fad pad are both released (Figures 7-14).

Figure 8. Division of short gastric vessels in the greater curvature.

Figure 9. Entrance into the lesser sac.

Figure 10. Division of the short gastric vessels cranially.

Figure 11. Adhesions between the pancreas and the posterior face of the stomach.

Figure 12. Division of retrogastric adhesions.

Figure 13. Division of cranial short gastric vessels.

Figure 14. Division of cranial short gastric vessels (continued).

Now is time to pass a 32 french bougie (12mm size) Figure 15.

Figure 15. Introduction of calibration bougie.

The assistant on the left side continues downwards from the incisura to the duodenum 2 or 3 cm far from the pylorus. At this point, a retro-duodenal tunnel is created by gentle dissection maneuvers starting from the inferior duodenal margin. The dissection is continued very close to the posterior wall of the duodenum, in a plane superior to the gastroduodenal artery. During this maneuver surgeon and assistants lift the stomach and a little window is created in the superior margin of the duodenum (gastrohepatic ligament) (Figures 16-23)

Figure 16. Division of the vessels from the incisura angularis downwards to the duodenum.

Figure 17. Division of the vessels from the incisura angularis downwards to the duodenum (continued).

Figure 18. Division of the vessels from the incisura angularis downwards to the duodenum (continued).

Figure 19. Division of the vessels from the incisura angularis downwards to the duodenum (continued).

Figure 20. Division of the vessels from the incisura angularis downwards to the duodenum (continued).

Figure 21. Dissection of the posterior wall of the duodenum.

Figure 22. Window is created in the superior margin of the duodenum.

Figure 23. Window is created in the superior margin of the duodenum (continued).

Once we have done the retro-duodenal tunnel, a 60mm endostapler is introduced by the surgeon on the right through the 12mm trocar and pass very gently along the tunnel and the duodenum is divided. The duodenum stapler line is reinforced with a 3/0 Monomax suture¹ (Figures 24-27).

¹ First, we create a sliding self-locking loop at the end of a 3/0 Monomax thread. The needle holder is passed by this loop, and grasps the suture close to the needle before entering the abdominal cavity. We introduce the needle holder by a 12 mm port and start the stitch taking first the omentum and then a sero-serosal stitch high up at the angle of His.

We hold again the suture close to the needle and pass the thread through the sliding loop. Then, the sliding loop and also the knot slide over the suture and this first stitch becomes self-locked with the principles of the Aberdeen knot: the more you pull, the more the knot is locked.

The rest of the suture is a sero-serosal running suture taking the omentum in every stitch and finally an Aberdeen knot ends the suture. We were concerned about the role of the two staples at the end of the thread of our running suture in the development of gastric leaks after LSG. These foreign bodies could be the origin of a hole at the angle of His and, potentially, the cause of the development of a leak at this level. The sliding self-locking first stitch is an easy maneuver that avoids the existence of foreign bodies in a delicate part of the stomach. The aim of this running suture is to stabilize the gastric tube on the one hand and to make hemostasis.

Figure 24. Section of the duodenum with linear stapler.

Figure 25. Section of the duodenum with linear stapler (continued).

Figure 26. The duodenal staple line is reinforced with a running suture.

Figure 27. The duodenal staple line is reinforced with a running suture (continued).

The 32-Fr bougie previously inserted is passed through the pylorus into the duodenum. Division of the stomach is started 2 cm above the pylorus, applying a 60mm violet or gold linear stapler inserted through the right side 12 mm port. Before every firing of the stapler the movility of the bougie is mandatory checked. Care must be taken in order to avoid stenosis at the level of the incisura.

Figure 28. Section of the stomach begins 2cm above the pylorus.

Gastric division progresses all along using 60 mm blue cartridges. At this point it is critical to expose properly the anterior and the posterior aspect of the stomach using lateral traction by the assistant on the left. This prevents a corkscrew shape of the sleeve as well as avoids leaving a large posterior fundus and the risk of postoperative gastroesophageal reflux. A methylene blue dye test is always done to check leaks at the esophagogastric junction and all along the staple line (Figures 28-34).

Figure 29. Gastric division progresses along the stomach.

Figure 30. Gastric division progresses along the stomach (continued).

Figure 31. Gastric division progresses along the stomach (continued).

Figure 32. Gastric division progresses along the stomach (continued).

Figure 38. Staple line reinforcement (continued).

We finish this part dividing the omentum for an easier and tension-free lifting of the jejunal loop. (Figure 39)

Figure 39. Division of the greater omentum.

b) Biliopancreatic Diversion Step

Patient is changed to Trendelenburg position and the surgeon and the assistants all move to the head of the patient.

Small bowel is measured using atraumatic marked forceps, starting from the ileocecal valve. A 100 cm common channel (CC) is identified and marked using one distal and two proximals clips. Further 250 cm are measured from this level, and a mesenteric window is created with the harmonic scalpel. Small bowel is then transected with a 60mm stapler. The bowel end located on the right (distal ileal end) is moved up supramesocolically becoming the alimentary limb (AL) (Figures 40-47)

Figure 40. Small bowel is measured using atraumatic marked forceps, starting from the ileocecal valve.

Figure 41. Small bowel is measured using atraumatic marked forceps, starting from the ileocecal valve (continued).

Figure 42. Small bowel is measured using atraumatic marked forceps, starting from the ileocecal valve (continued).

Figure 43. A 100 cm common channel (CC) is identified and marked using one distal and two proximal clips.

Figure 44. Further 250 cm are measured from this level.

Figure 45. A mesenteric window is created with the harmonic scalpel.

Figure 46. Small bowel is then transected with a 60mm stapler.

Figure 47. The bowel end located on the right (distal ileal end) is moved up supramesocolically becoming the alimentary limb (AL)

The bowel end located on the left (proximal ileal end) will be therefore the biliopancreatic limb (BPL). Next maneuver should be opening the BPL near the stapler line using the harmonic scalpel. Then, the surgeon follows the alimentary limb distally until the previous clips are identified.

A hand sewn termino-lateral anastomosis is done using two threads: one 15 cm. and another 13 cm. long 3/0 Monomax sutures. The long one is used for the posterior layer and the short one for the anterior. The suture is finished by tying both threads.

Figure 48. Opening of the BPL near the stapler line using the harmonic scalpel.

Figure 49. The surgeon follows the alimentary limb distally until the previous clips are identified.

Figure 50. Removal of the clips and performance of enterotomy.

Figure 51. A hand sewn termino-lateral anastomosis is done.

Figure 52. A hand sewn termino-lateral anastomosis is done.

Finally, the mesenteric defect is closed with a running 2/0 polypropylene suture (Figures 53-54),

Figure 53. Closure of the mesenteric defect.

Figure 54. Closure of the mesenteric defect (continued).

c) Duodenoileal Anastomosis Step

Again patient changes to anti-Trendelenburg position and the surgeon moves between the legs.

As we told before the AL had been moved up in an antecolic position.

We recommend using a 2/0 silk stitch to approximate the duodenum and the ileum, and then the assistant on the left side holds it and keeps the anastomosis stable (Figure 55).

Figure 55. Stich to approximate the duodenum and the ileum.

There are several ways to perform the anastomosis but we prefer a two layers hand sewn terminoterminal anastomosis.

The posterior layer is first done with a 3/0 monomax running suture, without incorporating the staple lines and ensuring the apposition of the two anastomotic stumps. We begin from the superior angle and progress till the end of both staple lines. We finish again with an Aberdeen Knot. The assistant on the left holds the end of this suture (Figures 56-57)

Figure 56. The posterior layer is first done with a running suture.

Figure 57. The posterior layer is first done with a running suture (continued).

Then, we open the duodenum and the ileum 1cm far from the staple line using the harmonic scalpel.

Figure 58. Opening of the duodenum and ileum.

Figure 59. Opening of the duodenum and ileum (continued).

Figure 60. Opening of the duodenum and ileum (continued).

For the inner layer we use two tied threads; one 21 cm and the other one 16 cm long. We use the long one for the posterior layer because we need to take big bites. On the other hand, the anterior inner layer is only seromuscular. The suture is finished by tying both threads and then the anastomosis is finally closed. The last layer (optional) is a 3/0 monomax running seroserosal suture.

Figure 61. Hand-sewn anastomosis (posterior inner layer).

Figure 62. Hand-sewn anastomosis (posterior inner layer).

Figure 63. Hand-sewn anastomosis (inner layer).

Figure 64. Hand-sewn anastomosis (posterior inner layer).

Figure 65. Hand-sewn anastomosis (anterior inner layer).

Figure 66. Hand-sewn anastomosis (anterior inner layer).

Figure 67. The suture is finished by tying both threads and then the anastomosis is finally closed.

Figure 68. The second anterior layer is optional.

We routinely place a naso-gastric tube and a methylene blue test is performed to check the anastomosis. (Figures 69-70)

Figure 69. Tightness test.

Figure 70. Tightness test (continued).

The excluded stomach is removed from the 12mm port on the right, and a Blake drain is left subhepatic, near the esophago-gastric junction.

We shut the 12mm access under direct vision using a 0 polipropilene Stitch (Figures 71-73).

Figure 71. Closure of the ports under direct vision.

Figure 72. Closure of the ports under direct vision (continued).

Figure 73. Closure of the ports under direct vision (continued).

Chapter 302

LAPAROSCOPIC BILIOPANCREATIC DIVERSION

Alberto Pagan^{*}, MD, PhD

Division of Esophagogastric and Bariatric Surgery,
Hospital Universitario Son Espases, Palma de Mallorca, Spain

ABSTRACT

Biliopancreatic shunt was originally described by Nicola Scopinaro in 1979 as an alternative to jejunoileal bypass for patients with severe obesity. The procedure consists of: 1) partial distal gastrectomy in which the duodenal stump is closed (or bypass of the distal part of the stomach), 2) transection of the small intestine approximately midway between the Treitz ligament and the ileocecal valve, 3) Roux-en-Y gastroenterostomy from the gastric pouch to the distal intestine creating a food limb, and 4) anastomosis of biliopancreatic limb with the alimentary limb 50 cm proximal to the ileocecal valve forms a common limb.

INTRODUCTION

Restrictive techniques such as sleeve gastrectomy are being imposed as those of choice in obesity surgery.

Malabsorptive surgery, and specifically biliopancreatic diversion, has an increasingly limited use, related to the metabolic complications derived from its use and what happens in the mid-long term. However, we believe that these complications are related to the systematic breach of dietary recommendations and supplementation of micronutrients of the patient and the lack of periodic clinical and analytical control.

^{*} Corresponding Author's Email: alberto.pagan@ssib.es.

INDICATION

The indications of this procedure are contemplated in the patient who associates the following clinical features:

- Superobese patients with binge eating disorders
- Superobese patients with major metabolic comorbidities (Type 2 diabetes mellitus, dyslipidemia)
- Superobese patient with severe gastroesophageal reflux diseases (GERD) documented with pH-metry

PREOPERATIVE PREPARATION

The preoperative work-up for bariatric surgery is performed by a multidisciplinary team, including surgeons, endocrinologists, dieticians, gastroenterologists, anesthesiologists and psychiatrists, who combine a medical, nutritional, and endocrinology workup to evaluate potential surgical candidates. Preoperative assessment included abdominal ultrasound, barium swallow, upper gastrointestinal endoscopy, analytic evaluation of the nutritional status and in selected cases a polysomnography, fibroscan, 24 ph-metry and manometry.

Anesthesia

An enhanced recovery after surgery (ERAS) programme is followed with an opioid-free anesthesia. Central vein and bladder catheters were not used.

SURGICAL TECHNIQUE

Instrumentation

1. Four 12 mm and one 5 mm ports
2. Nathanson liver retractor
3. 30° scope
4. Harmonic scalpel (Harmonic ACE; Johnson & Johnson)
5. Veress needle
6. Three atraumatic graspers
7. Suction-irrigator
8. Signia™ endo-stapler with Tri-Staple™ cartridges (Medtronic)
9. Clip applicator (optional)

PATIENT, PORT AND SURGEON POSITIONS

a) Patient Position

The patient is placed on the surgical table in a modified lithotomy position, requires leg loops and his left arm in complete abduction. The patient's fixation to the surgical table should be considered when Trendelenburg or accentuated Trendelenburg positions are required. Prior to the start of the procedure, mechanical compression devices are placed in the lower extremities.

b) Port Position

Pneumoperitoneum is performed by an umbilical puncture with a Veress needle in most cases and an intra-abdominal pressure of 14-16 mmHg is established.

The position of the trocars is identified by imaginary lines at the midclavicular and left anterior axillary levels (Figure 2 and 3). The usual number of ports is 4, although if there is difficulty in exposing the lesser gastric curvature in the presence of hepatomegaly, an additional subxiphoid trocar should be placed. We prefer the placement of 12-mm trocars to facilitate the eventual introduction of a linear endostapler by any of them.

Figure 1. Patient position.

Figure 2. Port position.

Figure 3. Port position.

c) Surgeon Position

In the inframesocolic time, the operating surgeon is placed on the left side of the patient. The assistants stand on the left side of the surgeon. In the supramesocolic time, the surgeon is placed between the patient's legs and the assistants on each side of the patient.

In the inframesocolic time the video monitor is in front of the surgeon. In supramesocolic time it is located in the patient's bedside. It is useful to have two video monitors (Figure 4, 5).

Figure 4. Surgeon position. Inframesocolic time.

Figure 5. Surgeon position. Supramesocolic time.

Figure 6. Optical trocar. Mixed access to the abdominal cavity.

PROCEDURE

a) Creation of the Pneumoperitoneum

Pneumoperitoneum is performed by an umbilical puncture with a Veress needle in most cases and an intra-abdominal pressure of 14-16 mmHg is established.

The first trocar to access the abdominal cavity is an optical port, allowing the visualization of the different layers of the abdominal wall.

There is the option of directly accessing the abdominal cavity without the optical trocar, although we consider it a less safe option.

b) Inframesocolic time

The biliopancreatic diversion procedure begins with the inframesocolic time.

The inframesocolic time begins with the measurement of the intestinal segments. To perform it, 2 pre-marked tweezers are used at 5 or 10 cm introduced by the trocars placed in both midclavicular lines.

It may be necessary to mobilize the patient with left lateral decubitus to contribute to the location of structures.

This measurement identifies and creates a common limb 60-70 cm proximal to the ileocecal valve that is marked with metal clips.

Figure 7. Intestinal measurement starts in ileocecal valve.

Figure 8. Marking with metal clips common intestinal loop segment.

Figure 9. Intestinal segment measurement. Alimentary limb preparation.

Figure 10. Intestinal segment measurement. Alimentary limb preparation.

Once predefined the future common limb, the measurement of the alimentary limb continues. This measurement is up to 300 cm, obtaining a total bowel segment of 360-370 cm from the ileocecal valve.

The bowel section is performed using a 45 or 60 mm mechanical linear cartridge at the surgeon's discretion using a mechanical endostapler (Signia™ with Tri-Staple™ 2.0 cartridges), obtaining the intestinal segment of the future alimentary limb and the intestinal segment of the biliopancreatic limb.

Figure 11. Intestinal segment measurement. Food intestinal loop preparation.

Figure 12. Signia™ with Tri-Staple™ 2.0 cartridges. Intestinal loop section.

Figure 13. Intestinal segments after section (distal, alimentary limb) (proximal, biliopancreatic limb).

Figure 14. Intestinal mesentery section.

Figure 15. Intestinal mesentery section.

The division of the mesenteric leaf must have a minimum length of 10 cm to favor the mobilization without tension of the intestinal loops.

The descent of the biliopancreatic segment is carried out by moving it over the mesentery of the future alimentary limb to the reference marked with hemoclips at the level of the ileum.

The performance of the jejunoileal anastomosis is facilitated with the confrontation of both intestinal segments by means of a stitch of reabsorbable material. The jejunoileal

anastomosis is performed with a 60 mm mechanical linear stapler, with the subsequent closure of the resulting intestinal orifices with a 2/0 reabsorbable running suture.

The inframesocolic time ends with the closure of the mesenteric leaves from their point of division, to avoid mesenteric gaps and future internal hernias. We use irreabsorbable material for its closure (Figure 21).

Figure 16. Distal displacement of the biliopancreatic segment.

Figure 20. Closure of enterotomy with running suture.

Figure 21. Closure of the mesenteric gap.

Figure 22. Final anatomical disposition of the jejunum-ileal anastomosis, common limb and alimentary limb.

c) In the Supramesocolic Time

It starts with the patient in an anti-Trendelenburg position. At this time the placement of a fifth trocar close to the xiphoid appendix to separate the left hepatic lobe is assessed.

Figure 23. Fifth subxiphoid trocar (optional).

Figure 24. Supramesocolic time. Gastric exposure.

Although the placement of the fifth trocar to separate the hepatic lobe is optional, we prefer its systematic placement to facilitate the performance of the gastrotomy with correct visualization and in a suitable location.

After gastric aspiration, the nasogastric tube should be removed to avoid being trapped with the mechanical suture.

We proceed first with the incision on the gastric lesser curvature until the omental transcurvature is reached. To facilitate this dissection, the first assistant's grip should be located in the margin of the gastric serosa near the mesogastrium.

Figure 25. Gastrolysis of the lesser gastric curvature.

Figure 28. Gastrolysis of the greater curvature.

Figure 29. Gastrolysis of the greater curvature.

Figure 30. Posterior gastric surface and transcavity view of the omentums.

The level of dissection is defined by the second vessel bifurcation of the left gastric artery.

Next, a wide gastrolisis of the greater gastric curvature is performed to facilitate the mobility of the proximal gastric portion. Once it is finished, the stomach can be easily mobilized to visualize the posterior surface, completing the dissection of the mesogastrium of the gastric minor curvature in its posterior part, when necessary.

Figure 31. Start of gastrotomy with distal gastric preservation.

Figure 32. Gastrotomy with the first linear cartridge.

Figure 32. Complete gastric transection.

Figure 33. Gastrotomy completed (two cartridges).

The gastric section is made by means of two mechanical linear staplings, that are introduced through the trocar on the anterior axillary line at the level of the avascular part of the greater curvature in the direction of the gap made in the lesser curvature, preserving the distal stomach to eliminate the risk of the duodenal stump leak. Typically, two 60 mm endostapler cartridges are necessary.

Figure 34. Gastrotomy at the staple line level.

Figure 35. Enterotomy of the alimentary limb.

Figure 36. Ascent of the alimentary limb.

A complete section of the stomach should be performed, not a simple stapling of the organ, with an evident separation of the proximal and distal gastric portions to avoid repermeabilization of the staple lines.

An enterotomy of the alimentary limb is performed and one of the parts of the endostapler is introduced in it. This helps to ascend the bowel limb to the proximity of the gastric pouch. A gastrotomy is performed in the posterior face of the pouch at the end of the staple line, close to the greater curvature. The other part of the endostapler is introduced through this gastrotomy and the device is closed to perform the anastomosis.

Figure 37. Ascent of the alimentary limb.

Figure 38. Approximation of the alimentary limb to the gastric pouch.

Gastrojejunal anastomosis is made using two cartridges, to obtain a wide anastomosis and prevent future stenosis or inadequate gastric emptying.

After the gastrojejunostomy, we routinely check the presence of bleeding in the staple line.

The gastroenteric gaps can be closed by means of a 60 mm mechanical linear stapling (Figure 42) or with a running suture of 2/0 reabsorbable material.

Figure 39. Gastrojejunal anastomosis.

Figure 40. Enlargement of the gastrojejunal anastomosis with a second cartridge.

Figure 41. Gastrojejunal anastomosis check. Visulation of the staple line.

Figure 42. Gastrojejunal enterotomy closure with linear stapling.

Figure 43. Checking the tightness of the gastrojejunal anastomosis.

After performing the anastomosis, it is optional to insufflate the stomach through the nasogastric tube, introducing methylene blue or air to check the tightness of the suture. After checking the tightness, the nasogastric tube is removed.

Finally, the tension of the mesentery in its antecolic ascent and the absence of bleeding at that level is checked.

Abdominal drains are not routinely placed and are indicated at the surgeon's discretion.

ABSTRACT

The liver, a principal metabolic organ, is the target of metabolic disorders which may lead to the development of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH). NAFLD and NASH represent different stages of the same disease, and appear to be multifactorial. Etiopathogenesis is complex and currently the underlying mechanisms are not completely understood; there have been different hypotheses describing the pathogenesis; the main three are: the “two hits,” “three hits,” and “multiple hits” hypotheses. Here, we explain all the factors that seem to influence the development and the outcome of this disease.

Keywords: liver-histology, NASH/NAFLD etiopathogenesis, two-hits hypotheses, three- hits hypotheses, multiple-hits hypotheses

INTRODUCTION

The liver, a principal metabolic organ, is frequently the target of various metabolic disorders, which may lead to the development of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH). These conditions are associated with obesity and insulin resistance, and they are considered a hepatic manifestation of the Metabolic Syndrome (MS).

Also, liver disease can lead to systemic metabolic abnormalities. NAFLD/NASH is an emerging risk factor for obesity, dyslipidemia, type 2 diabetes, cardiovascular disease, and chronic kidney disease.

The term NAFLD includes a spectrum of fatty liver diseases ranging from simple steatosis to NASH and cirrhosis.

NAFLD is defined as an accumulation of fat in the hepatocytes when excessive drinking of alcohol or any other secondary cause is not present.

NAFLD is considered benign and reversible. Patients who suffer only hepatic steatosis may have a good prognosis in the long term, 10–20% develop NASH, defined as steatosis with hepatic inflammation, hepatocyte injury with or without fibrosis. NASH can progress to more severe stages such as cirrhosis and hepatocellular carcinoma (HCC).

Currently, NAFLD/NASH is one of the most prevalent chronic liver diseases, and is emerging as a global public health threat

THE LIVER

The liver is both an exocrine and endocrine gland, located at the “crossroad” of the digestive tract and the rest of the organism. Some of the main functions of an adult liver include:

- bile production, as the main exocrine function,
- conservation of metabolic balance,
- glycogen storage,
- drug degradation,
- toxin degradation,
- plasma protein synthesis,
- vitamins (A, D and K) processing, and storage,
- iron storage, metabolism, and homeostasis,
- immunoglobulin A secretion,
- secretion of growth actors.

Therefore, the scope of liver disease consequences is large, due to the dependence of other organs on the liver’s metabolic functions.

In the embryo, in the 4th week of gestation, the liver starts developing from the hepatic diverticulum, which is an endodermal evagination of the anterior primitive intestine.

Adult liver cells proceed from different embryonic origins:

- the liver bud arises from the anterior intestine, giving place to hepatocytes and the choledocus epithelial lining.
- umbilical and vitelline veins are the origin of vascular sinusoids.
- from the septum transversum: stroma and hepatic capsule, hematopoietic cells, Kupffer cells, smooth muscle, and connective tissue of bile ducts.

During the fetal period, the liver has a double role: bile synthesis (from the 12th week) and hematopoiesis. From the first gestational weeks, groups of hematopoietic cells appear between hepatocytes and the blood vessel walls. The liver assumes its role as hematopoietic organ from the third month to the seventh month of gestation, when such function begins to decrease and the bone marrow becomes the main hematopoietic organ, thus causing liver volume to decrease from 10% of body volume in a 10-gestational week embryo to less than 5% of total body volume in a full-term fetus.

Anatomically, in an adult, the liver is coated with Glisson's capsule, a fibrous connective tissue capsule, and the visceral peritoneum, a serous cover.

Macroscopically, it is divided into four lobes: right, left, quadrate, and caudate lobe or Spiegel's lobe. Such division is only important topographically. The division in functional or surgical segments, based on blood supply and biliary drainage, is more important.

In order to understand the liver's functions and pathology, its vascularization should be described.

Liver Vascularization

This organ presents double irrigation: the portal vein and the hepatic artery (branch of the celiac trunk). They both access through the hepatic hilum. The liver receives blood that has previously irrigated the intestine, the spleen and the pancreas, and thus contains:

- nutritional and toxic substances proceeding from the intestine
- erythrocyte and erythrocyte degradation products from the spleen
- endocrine secretions from the pancreas
- enteroendocrine cell secretions from the digestive tract

The liver is interposed in the course of the blood vessels transporting the substances absorbed in the digestive tract. It is the first organ receiving metabolic substrates and nutritional substances. But it is also exposed to toxic components that may have been absorbed.

Around 75% of irrigation proceeds from the portal vein that carries venous blood that has poor oxygen concentration. Since the blood from the two sources is mixed just before perfusing the hepatocytes, they are never fully exposed to oxygenated blood.

Inside the liver, distribution branches of the portal vein and the hepatic artery deliver blood to sinusoid capillaries which will irrigate the hepatocytes. Branches of the portal vein, arteries, and biliary drainage (which disgorge in a common hepatic duct) flow jointly and create the "portal triad."

Sinusoid capillaries flow in close contact with hepatocytes, disgorge into a central or centrolobular vein, which in turn drains into supralobular veins. The blood leaves the liver through suprahepatic veins, which disgorge in the inferior vena cava.

HISTOLOGICAL ORGANIZATION OF THE LIVER

The liver is formed by the parenchyma, which consists of trabeculae or chords of hepatocytes that are organized in only one cell of thickness in adults. These chords are separated by sinusoid blood capillaries with a lumen of around a 15 micron diameter. The wall is formed by a single layer of endothelial cells with a large number of fenestrations and surrounded by a discontinuous basal membrane. Such organization allows for direct contact among the substances circulating in the blood and the cells forming and surrounding capillaries.

The stroma is a connective tissue connected with the fibrous capsule of Glisson. Blood vessels, lymph vessels, nervous branches, and bile ducts can be found in it. In the connective tissue of the narrow space between hepatocytes and sinusoid capillaries, reticular fibers (or type III fibers) are predominant, whereas collagen I is predominant in portal spaces (Figure 1).

Figure 1. Human Liver. The stroma of liver is constituted by a reticular connective tissue with collagen III, impregnated in black with silver carbonate. As seen in the image A, these fibers increase their proportion in the portal spaces(ES). V: centrilobular vein. Del Rio Ortega Silver Carbonate Technique. 50x. In image B, we can observe in more detail the reinforcement of collagen III around the centrilobular vein. Ortega Silver Carbonate Technique. 200x.

Liver Lobules

There are three possible histological models to describe the structure of the liver: classic lobule, portal lobule, and liver acinus (Figure 2).

Classic Lobule

This is the classical and easiest-to-see mode to consider hepatic organization. It is based on the distribution of the portal vein and the hepatic artery branches inside the organ, and the route followed by the blood coming from these vessels when it perfuses the hepatocytes.

In a hepatic classic lobule, cuts present a more or less hexagonal tissue mass. Each lobule measures 0.2 x 0.7 mm. It is composed of one-cell-thick plates of anastomosed hepatic trabeculae, separated by liver sinusoids. There is a vein at the center, the post-sinusoidal hepatic venule, referred to as the central vein or centrilobular vein, in which sinusoids discharge.

Figure 2. Scheme with the three types of liver lobules.

Hepatocyte plates and the corresponding sinusoids have a radial disposition from the centrilobular vein towards the periphery of the lobule. In the hexagon angles, there are the portal spaces with triads surrounded by loose connective tissue, which is continuous with the Glisson fibrous capsule.

Portal Lobule

Exocrine liver functions stand out, particularly in bile secretion. Therefore, the morphological axis is the interlobular bile duct of the portal triad of the classic lobule.

The external edges are the imaginary lines mapped out connecting the three centrilobular veins that lay closest to that portal triad. These lines define a tissular region similar to a triangle, which includes those portions of the three classic lobules that secrete bile. Bile is drained in the axial bile duct (Figure 3).

Liver Acinus

This is the structural unit that best groups and coordinates blood perfusion, metabolic activity, and hepatic pathology. This structure allows for a description of the liver's exocrine function.

The acinus has a rhomboid shape. The minor axis is defined by the terminal branches of the portal triad, which coincide with the limits of two classic lobules, and the main axis is a perpendicular line drawn between the two centrilobular veins closer to the minor axis. Therefore, in a two-dimensional view, the liver acinus occupies part of two contiguous classic lobules.

Based on this organization, hepatocytes in each acinus are described as lying in three concentric elliptical zones that surround the short axis:

- zone 1: closest to the short axis and the irrigation coming from the portal vein and the hepatic artery branches. This zone corresponds to the periphery of classic lobules.
- zone 3: the most distant to the short axis and the closest to the centrilobular vein. This zone corresponds to the center of the classic lobule, whose hepatocytes surround the centrilobular vein.
- zone 2: between zone 1 and 3, but with no clear limits.

Figure 3. A. Histological image of a human liver, being complicated the delimitation of the lobules (dashed line). We can appreciate the presence of a centrilobular vein (arrow) and portal space around it (E). Hematoxylin-Eosin, 100x. B. Here we can observe a portal space of a human liver. Within the dashed line, portal space and its structures: vein(V), artery (yellow arrow) and bile duct (white arrow). H: liver parenchyma. Hematoxylin-Eosin. 250X.

The division of hepatic parenchyma in zones is indispensable for the description and interpretation of the hepatic lesion distribution due to ischemia, or to exposition to toxic substances, in order to assess the level of tissue degeneration and cell regeneration in every clinical situation.

Due to the sinusoidal blood flow, the oxygen gradient, metabolic activity of hepatocytes and hepatic enzyme distribution vary in the three zones.

Zone 1 cells are the first to receive oxygen, nutrients and toxins from the sinusoidal blood. Thus, they are the first to exhibit morphological alterations after a bile duct obstruction. These cells are also the last to die if there are circulation disorders, and the first to regenerate.

Zone 2 cells have morphological and functional characteristics, as well as responses, that are intermediate between cells in Zones 1 and 3.

Zone 3 cells are the first to suffer ischemic necrosis (centrilobular necrosis) in situations where perfusion is altered, and the first to accumulate lipids. They are the last to respond to toxic substances and biliary stasis.

In Zones 1 and 3, normal variations of enzymatic activity, the amount and dimensions of cytoplasmic organelles, and the size of glycogen cell deposits can be confirmed.

Liver Cells

Hepatocytes

They represent 80% of the parenchyma (Figure 4). They are big polyhedral cells, measuring around 20 x 30 microns. Their big nuclei are located in the cell center, and several are binucleated. The mean life of these cells is relatively long, around 5 months, and they have a huge capacity to regenerate.

200 to 300 *peroxisomes* can be found in the cytoplasm of each cell. Their function is similar to that of mitochondria, and they are a site of important oxygen consumption. A large number of oxidases (which generate hydrogen peroxide), catalases (enzymes degrading

hydrogen peroxide to oxygen and water), D-amino acid oxidase, and alcohol dehydrogenase can be found in them. Peroxisomes intervene in the degradation of fatty acids (through beta-oxidation), in glycogenesis, and in purine metabolism. They also participate in the detox processes that take place in the liver, such as alcohol detox.

The *Smooth Endoplasmic Reticulum* (SER) of hepatocytes can be very extensive, but it will depend on the functional moment. It contains enzymes that participate in the degradation and conjugation of toxins and drugs, cholesterol synthesis enzymes, and enzymes of lipoproteins lipid component. In overburdened liver conditions, due to drugs or hormones, the synthesis of new SER membranes and their associated enzymes is induced. Hypertrophy is also experienced after the administration of alcohol, drugs (phenobarbital, anabolic steroids and progesterone) and certain chemotherapy agents.

Likewise, the *Golgi apparatus* in these cells is very developed with up to 50 dictyosomes, each composed of 3-5 piled cisterns.

Figure 4. A. Human liver lobule (dashed line). With this histological technique, the stored glycogen in the hepatocytes is highlighted, colored in clear carmine. Carmin de Best Technique. 50 X. B. High-magnification image of the previous preparation. The sinusoids, the hepatocyte cords, as well as the nuclei of the sinusoidal cells (thin white arrows), the Ito cells (yellow arrows) and the Kupffer cells (green arrows) are observed. Carmin de Best Technique. 400 X.

Lysosomes in hepatocytes concentrate close to the bile canaliculus. They can also be a site for normal storing of ferritin, and a ferric accumulation site in certain diseases, due to an excessive deposition.

Macrophages Present in the Liver

Macrophages belong to the phagocytic mononuclear system. Hepatic macrophages consist of resident macrophages called Kupffer cells (KCs) and macrophages that arise from bone marrow-derived monocytes after a stimulus.

KCs lean on the endothelium, and their extensions cross the whole sinusoidal lumen. These are common cells in the endothelial lining of sinusoids, where they create a barrier. They present abundant lysosomes, phagocyte particles and microorganisms that arrive in the hepatic lobules through the blood.

They participate in the final degradation of certain aged or damaged erythrocytes. Erythrocyte and iron fragments, in the form of ferritin, can be observed in their cytoplasm.

They represent a cell of innate immunity. KCs are the body's primary line of defense against microorganisms. Their location is optimal for carrying out their functions inside the

liver. During liver injury, KCs initiate the immunological response by rapidly secreting cytokines and chemokines, which induce the recruitment of other immune cells, including monocytes, into the liver. Both populations of macrophages produce proinflammatory and anti-inflammatory cytokines, contributing to chronic inflammation such as that seen in alcoholic liver disease, NAFLD, NASH and other pathological conditions affecting the liver.

Perisinusoidal Space or Space of Disse

This is a zone for intercellular exchange of substances between the blood and hepatocytes. It is defined as the space between the basal surfaces of hepatocytes and the basal surfaces of endothelial cells and Kupffer cells that line the sinusoids. Because of the large gaps in the endothelial layer and the absence of the continuous basal lamina, no significant barrier exists between the blood plasma in the sinusoid and the hepatocyte plasma membrane.

Because of the broad fenestrations between endothelial cells and the discontinuity in the basal membrane, there is no physical barrier between sinusoid blood and the plasma membranes of hepatocytes. Proteins and lipoproteins synthesized by hepatocytes are directly transferred into the blood through this space. This pathway is for liver secretions other than bile.

Ito Cells (or Stellate Cells)

They can also be found in these spaces. Their origin is mesenchymal, and they are the primary storage site for hepatic vitamin A. In certain liver diseases, chronic inflammation, or cirrhosis, Ito cells lose their ability to store lipids and vitamin A, and they differentiate into cells with characteristics of myofibroblasts, with capacity to synthesize collagen. These cells seem to play an important role in hepatic fibrogenesis. They synthesize and deposit collagen I and II in the portal space, as well as in the connective zone surrounding the centrilobular vein.

An increase in perisinusoidal fibrous stroma is an early sign of liver response to toxic substances.

The cytoplasm of cells contains elements of the contractile apparatus, such as α -actin filaments or desmin intermediate filaments. In situations where contraction of these cells is stimulated, the vascular resistance will be empowered within the sinusoids due to their lumen reduction, leading to portal hypertension. Furthermore, Ito cells participate in extracellular matrix remodeling during recovery from liver injury.

In the fetal liver, islands of hematopoietic cells appear in this space. In cases of chronic anemia in the adult, hematopoietic cells may reappear.

Beyond all that has been explained in this section, the fact that the liver depends on a huge functional reserve remains to be highlighted, and in almost all diseases, except for those causing death, regeneration takes place. After resection of 75% of the liver, there is a small hepatic deterioration, and regeneration restores the liver mass in few weeks. When a massive hepatocellular necrosis occurs, but the connective tissue web remains intact and the patient survives the metabolic aggression of liver failure, tissue restoration may be almost perfect.

ETIOPATHOGENESIS

Etiopathogenesis is complex and currently the underlying mechanisms are not completely understood; NAFLD and NASH represent different stages of the same disease, and appear to be multifactorial. They occur in response to a chronic inflammatory liver state accompanying obesity, insulin resistance, hepatic steatosis, and oxidative stress. The most progressive forms of NAFLD have been related to metabolic syndrome (ME) and obesity. Both liver parenchymal and nonparenchymal cells are affected.

There have been different hypotheses describing the pathogenesis of NAFLD/NASH. The main three are: the “two hits,” “three hits,” and “multiple hits” hypotheses.

The classical pathogenetic pathway, originally proposed in 1998, was described as the “two hits hypothesis.” This theory stated that damage to the liver tissue begins through aberrant triglyceride accumulation, *the first hit*, which induces *the second hit*, the activation of inflammatory mediators, lipotoxic metabolite-induced mitochondrial dysfunction and oxidative stress. These aggressions lead to steatohepatitis and fibrosis.

The “three hits” theory involves inadequate hepatocyte proliferation after cell death triggered by aberrant lipid accumulation and excessive oxidative stress.

Finally, the “multiple hits” hypothesis involves organ-organ interactions in NASH; inflammatory mediators released from adipose tissue and the liver/gut axis are implicated in NASH pathogenesis. In this model, environmental, metabolic and genetic factors contribute to the development and progression of NASH by affecting diverse organs such as the liver, intestines, and adipose tissue. More specifically, excess caloric or inappropriate intake (environmental factor) increases toxic free fatty acid (FFA) and lipid metabolites (lysophosphatidylcholine (LPC), cholesterol and ceramide) in hepatocytes, leading to hepatic steatosis and hepatocyte sublethal/lethal injuries. Subsequently, hepatocyte-derived cytokines/chemokines and damage-associated molecular patterns (DAMPs) stimulate Kupffer cells (KC) (which promote inflammatory response) and hepatic stellate cells (HSC) (stimulate fibrotic response); this leads to the development of inflammation and fibrosis in the liver. Free fatty acid (FFA) and lipid metabolites derived from diets or synthesized *de novo* also activate KC and HSC. In addition, insulin resistance and obesity (metabolic factor) influence organ crosstalk between the intestine/adipose tissue and the liver, contributing to the development and progression of NASH.

Various studies suggest that variations in several genes related to hepatic lipid metabolism are associated with increased hepatic steatosis in human NAFLD subjects (PNPLA3 (patatin-like phospholipase domain-containing protein 3), TM6SP2 (transmembrane 6 superfamily member 2), and FADS (fatty acid desaturase)). Factors influencing NAFLD and NASH, and collaborating in their development are discussed next.

Lipid Accumulation in the Hepatocytes

In NAFLD, cell lipid accumulation and the subsequent steatosis may result from several mechanisms: excess fat ingestion, increased fat synthesis, decreased fat export and decreased fat oxidation.

Sedentary lifestyle, too caloric diets or inappropriate intake as diets with high glucose, high fructose, high fat or high cholesterol are environmental factors associated with hepatic steatosis and NAFLD/NASH.

In the case of excess dietary glucose or fructose, they enter the liver through the bloodstream after uptake in the small intestine and are subsequently utilized for the production of hepatic triacylglycerol (TG) via *de novo* fatty acid synthesis, and become a source of hepatic glycogen storage. When there is excessive free fatty acid (FFA) accumulation within hepatocytes generate toxic lipid metabolites and cause hepatocyte injury, consequently, initiation of NASH.

Lipid metabolites such as palmitic acid, lysophosphatidylcholine (LPC), ceramide, and free cholesterol are considered mediators of hepatocellular lipotoxicity and they contribute to the development and progression of NASH. High concentrations are found in the livers of human subjects with NASH.

Palmitic acid has been reported to trigger oxidative stress, endoplasmic reticulum and mitochondrial stresses, causing lipotoxicity and cell death.

LPC generated from palmitic acid triggers mitochondria-dependent apoptotic machinery.

Ceramide synthesized from palmitic acid also causes mitochondrial impairment of the mitochondrial respiratory chain and increases mitochondrial membrane permeability leading to hepatocyte cell death.

Free cholesterol can induce hepatocyte necrosis/apoptosis by depleting mitochondrial glutathione, and can induce hepatocyte necrosis by generating cholesterol crystals within lipid droplets.

Endoplasmic Reticulum (ER) Stress

Endoplasmic reticulum (ER) Stress is associated with the development of NAFL and progression to NASH through direct cell injury and indirect changes in cell signaling pathways.

In situations of hyperinsulinemia and hiperlipidemia, ER stress causes inflammation, apoptosis, and mitochondrial dysfunction.

Increased dietary intake of FFA, *de novo* lipogenesis and adipose lipolysis, together with impaired FFA oxidation, causes an increase in the flux of FFAs within hepatocytes.

Excessive lipid accumulation causes hepatocellular lipotoxicity via cellular and organelle oxidative stresses including endoplasmic reticulum (ER) stress and mitochondrial dysfunction, leading to hepatocyte cell death.

Furthermore, *chronic* ER stress increases the production of reactive oxygen species (ROS). ROS induces activation of nuclear factor $\text{I}\kappa\text{B}$ - β /NF- κB , a master regulator in the production of proinflammatory cytokines (IL-1- β , TNF- α and IL-6).

In addition, chronic ER stress results in hepatic lipid accumulation via activation of *de novo* fatty acid synthesis in a manner dependent on ER stress-sensing pathways suggesting that a vicious cycle between ER stress and hepatic steatosis may promote the development and progression of NAFLD/NASH.

Activation of Inflammatory Mediators

Steatosis is strongly associated with chronic hepatic inflammation. Different immunological mechanisms are implicated in the NAFLD progression: innate immunity, adaptive immunity, NLRP3 inflammasome activation. As evidence, portal inflammatory infiltrates in human NASH livers are characterized by broad inflammatory cell markers: CD68, CD3, CD8, CD4, CD20, neutrophil elastase, matrix metalloproteinase 9 and interleukins.

Innate Immunity in NAFLD/NASH: Kupffer Cells (KC) and Hepatic Stellate Cells (HSC) in NAFLD/NASH

In NAFLD and its evolution to NASH, the innate immune system is activated by different factors and through different pathways. This creates a vicious cycle difficult to break. Hereunder, some of these factors are discussed.

1. In response to excessive lipids, hepatocytes produce chemokines and pro-inflammatory cytokines (TNF- α , IL-6 and IL-1 β); they act on non-parenchymal cells such as KCs and HSCs, which contribute to the progression of NASH.
2. Lipotoxic fatty acids such as palmitic acid and ceramide can activate Kupffer cells and subsequently promote the production of pro-inflammatory cytokines such as CCL2 which recruit more peripheral macrophages, CXCL16 to recruit natural killer T cells, and CXCL1/2/8 to recruit neutrophils (TNF α and IL-6)

In this way, Kupffer cells and recruited innate immune cells coordinately aggravate inflammation in the liver.

Moreover, Kupffer cells and infiltrating macrophages produce several cytokines such as TGF β , Galectin- 3, platelet-derived growth factor, TNF- α and IL-1 β that are able to activate quiescent HSCs and increase their proliferation. More specifically, palmitic acid-induced TNF- α and IL-1 β in infiltrating macrophages can cause lipid accumulation and insulin resistance in hepatocytes. Macrophages activated by the palmitic acid, by secreting TNF- α and IL-beta, generate lipid accumulation and insulin resistance in hepatocytes.

3. Apoptotic or necrotic hepatic cells trigger signals for NASH promotion. They release inflammatory cytokines, damage-associated molecular patterns (DAMPs), ATP, uric acid or mitochondrial DNA. DAMPs can cause hepatic inflammation and fibrosis by activating KCs and HSCs via paracrine or endocrine actions.
4. Elevated hepatic expression of inflammatory cytokines such as TNF- α , interleukin-6 (IL-6) and interleukin 1-beta (IL-1 β), and activated Kupffer cells, start up the I κ B/ β /NF- κ B signaling pathway. Both inflammation and I κ B/ β /NF- κ B activation promote carcinogenesis and may also play a key role in hepatocellular carcinoma (HCC) development.
5. Finally, activated Kupffer cells, infiltrating macrophages and hepatocytes secrete NLRP3 inflammasome-dependent IL-1 β , which plays a crucial role in the progression of NAFLD/NASH.

The Involvement of Adaptive Immunity: Role of Lymphocytes in NASH

The mechanism involved in the initiation of inflammation in NASH pathogenesis is very similar to other organs. In the initial phase, the resident macrophages secrete chemokines, which recruit CD4+/CD8+ T lymphocytes and NKT cells to the tissue, which enhance macrophage activation and proinflammatory mediator release. Both macrophages and lymphocytes represent the most frequent inflammatory infiltrates of NASH livers. It should be stressed that, in human NASH liver biopsy sections, the portal tract infiltrates are dominated by CD8 (+) lymphocytes.

The B cells also play a critical role in NASH pathogenesis. Lipid peroxidation products from phospholipid oxidation interact with B lymphocytes and are one of the sources of antigens able to promote an adaptive immune response in NASH. As evidence, 40%–60% of patients with NASH have circulating antibodies against lipid peroxidation-derived antigens and the high titers of these antibodies are in parallel with increased risk to develop advanced liver fibrosis.

Insulin Resistance (IR) in NAFLD/NASH Development

Metabolic factors such as obesity, dyslipidemia, and IR come together with NAFLD. In individuals with IR who present excess visceral fat, the influx of FFAs to the liver is increased, thus leading to both triglyceride accumulation and direct lipotoxicity.

Hyperinsulinemia or hyperglycemia, a key feature of insulin resistance, increases hepatic de novo fatty acid synthesis.

So, because of IR, there is greater influx of FFAs to the liver: these undergo β -oxidation or esterification with glycerol to form triglycerides. Additionally, FFAs are able to cause toxicity through directly increasing oxidative stress and activating inflammatory pathways.

On the other hand, insulin resistance in adipose tissue impairs the ability of insulin to suppress lipolysis; consequently, FFAs released from adipose tissue are transported into the liver (FFAs from adipose tissue contribute to 60% of hepatic lipid accumulation).

NAFLD also contributes towards a worsening of IR and the cumulative effect generates a vicious cycle of IR and NAFLD worsening each other. Several abnormalities intrinsic to NAFLD impair insulin receptor signaling, especially: FFAs, tumor necrosis factor- α (TNF- α), nuclear factor kappa B (NF- κ B), ceramide, Jun N-terminal kinase 1 (JNK1), suppressors of cytokine signaling (SOCS) and cytochrome CYP2E1.

Altered Hepatocyte Proliferation and NAFLD/NASH

Dead hepatocytes are normally replaced by replication of mature hepatocytes so normal liver function is maintained.

In NAFLD, high levels of oxidative stress causes disruption to the regenerative process; mature hepatocytes present impairment of their replication process, and when cell death occurs, the hepatic progenitor cells (HPC) proliferate. These cells have the capacity to differentiate into either hepatocytes or cholangiocytes and may be involved in carcinogenesis

relating both to hepatocellular carcinoma and to cholangiocarcinoma, which are the final and most severe consequences of this clinical picture.

It is observed that there is a strong association between expansion of HPCs and a ductular reaction in liver biopsy specimens in NASH cases. The extent of ductular reactions strongly correlates with the degree of fibrosis, suggesting that HPC expansion/ductular reaction do play an important role in stimulating progressive periportal fibrosis.

Inter-Organ Crosstalk in NAFLD/NASH

Adipose tissue and the intestines have a very important role in NAFLD and NASH pathogenesis.

Adipose Tissue-Liver Axis and NASH

Obesity and the associated insulin resistance contribute to the hepatic steatosis, NAFLD and NASH. As we previously mentioned, impaired suppression of insulin-mediated lipolysis in adipose tissue leads to hepatic steatosis through increased fatty acid uptake of hepatocytes. In addition, inflammation in adipose tissue affects hepatic inflammation.

Intestine-Liver Axis and NASH

As discussed below, the impairment of this axis is an important causal factor in the pathogenesis of obesity related steatosis, NAFLD/NASH, liver cancer and diverse liver diseases.

Intestinal permeability and increased gut microbial translocation contribute to the inflammatory pathway involved in nonalcoholic steatohepatitis (NASH) development.

Numerous studies have investigated the association between increased intestinal permeability and NASH.

A meta-analysis was performed by Luther J et al. In 2015, in order to confirm that, they compared the rates of increased intestinal permeability in patients with NASH with healthy controls. NASH patients are more likely to have increased intestinal permeability compared with healthy controls.

In mice, an experimental high fat diet, like NAFLD/NASH diets, induces a decrease in Paneth cell area and a lower production of antimicrobial peptides by these cells, reduced Goblet cell number and their mucin secretion, while intestinal permeability is increased. HFD-fed mice are more susceptible to experimental colitis, severe colonic inflammation, accompanied by the expansion of selected pathobionts such as *Atopobium* sp.

Consequently, bacteria or bacterial products are able to reach the liver through the portal vein. In the liver, conserved motifs of bacteria and bacterial products are recognized by receptors of Kupffer cells, infiltrating macrophages, and HSCs. Lipopolysaccharides and bacterial DNA stimulate multiple signaling cascades via interactions with TLR receptors leading to hepatic steatosis, inflammation, and fibrosis in the liver.

Evidence suggests that lipid intermediates derived from the intestine trigger the development of NAFLD/NASH.

One of the pathways is via intestinal hypoxia-inducible factor HIF-2 α , which regulates ceramide metabolism by positive expression of *Neu3*, the gene encoding neuraminidase 3.

Human-intestine biopsies from individuals with and without obesity revealed that intestinal HIF-2 α signaling was positively correlated with body-mass index and hepatic toxicity. This correlation was verified in mice with an intestine-specific disruption of HIF-2 α , in which high-fat-diet-induced hepatic steatosis and obesity were substantially lower as compared to control mice. Intestine HIF-2 α inhibition with specific inhibitor markedly reduced intestine and serum ceramide levels.

Gut Bacterial Overgrowth in the Pathogenesis of NASH

Gut microbiota analysis revealed that individuals with NAFLD have a lower percentage of *Bacteroides* with higher levels of *Prevotella* and *Porphyromonas* species compared to healthy controls.

Another study found that the inflammasome-mediated dysbiosis of gut microbiota exacerbates hepatic steatosis and inflammation through enhancing liver TNF- α production.

A murine model of high-fat diet-induced (HFD-induced) NAFLD was used. This study demonstrated that gut microbiota influences NAFLD pathogenesis by regulating the bile acid/intestinal FXR (intestinal farnesoid X receptor) axis that alters the ceramide pathway in the liver and, combined with reduced bacterial fermentation in the gut, results in decreased hepatic lipids. Furthermore, this work reveals an essential role for intestinal FXR in controlling liver lipid metabolism and provides a potential therapeutic strategy for the prevention of disease progression in patients with NAFLD.

Hepatic macrophages play a critical role in maintaining immune homeostasis of the liver.

The liver is constantly exposed to antigens and low levels of endotoxins from the gut since 75% of the liver's blood is supplied from the portal vein.

In normal conditions, small amounts of endotoxins from gut bacteria enter the liver and most of them are eliminated by KCs.

However, the altered composition of microbiota, gut permeability increases and hyper-responsibility of KCs to the gut-derived endotoxin can interrupt this tolerance.

M1 macrophages are abundant and play a critical role in driving inflammation and hepatocyte injury. Macrophage M2 activation is initiated by cytokines IL-10 and IL-4 releasing from prolonged ER stressed hepatocytes.

Macrophage in NASH is associated with toll-like receptor TLR4 activation. During liver injury, macrophages release proinflammatory cytokines such as IL-1 β , TNF- α , and IL-6 through the activation of TLR4.

When prolonged, this contributes to T cell activation and results in hepatocyte death and subsequent activation of HSCs.

During NASH, liver macrophages engulf an excessive amount of oxidized low-density lipoprotein and form "foam cells." These macrophage-derived foam cells predominantly contain enlarged lysosomes filled with cholesterol and cholesterol crystals. Increased cholesterol storage inside lysosomes of KCs is associated with hepatic inflammation.

ABSTRACT

Obesity, besides being a common risk factor for a wide range of diseases, such as diabetes, cardiovascular disease or cancer, it is associated with an increased risk of developing non-alcoholic fatty liver disease (NAFLD). It also contributes to the progression of different types of liver diseases, including non-alcoholic steatohepatitis (NASH) and even cirrhosis.

The prevalence of NAFLD has risen in the last decades together with obesity and type 2 diabetes mellitus, becoming the most common chronic liver disease worldwide.

The treatment of NAFLD is based on weight loss, which can be achieved by lifestyle modifications, pharmacologic therapy or bariatric surgery.

Keywords: non-alcoholic fatty liver disease, non-alcoholic steatohepatitis, morbid obesity

INTRODUCTION

Obesity is a disease that usually begins in childhood and it is becoming more frequent each day. It occurs as a result of an imbalance between calorie intake and energy expenditure. Obesity is defined by a body mass index (BMI) $\geq 30\text{kg/m}^2$ and morbid obesity as a BMI $\geq 40\text{kg/m}^2$. There are many factors involved in the development of obesity, including genetic

* Corresponding Author's Email: manuel.duran@hospitalreyjuancarlos.es.

and environmental factors. These factors can lead to the excessive accumulation of body fat and thereby to the onset of metabolic syndrome. Obesity reflects also a generalized proinflammatory state.

Recent research has shown that obesity, besides being a common risk factor for a wide range of diseases, including diabetes, cardiovascular disease and cancer, is associated with an increased risk of non-alcoholic fatty liver disease (NAFLD). Scientific evidence also demonstrates that obesity contributes to the progression of different types of liver diseases. Actually, it represents a risk factor for developing hepatocellular carcinoma (HCC) together with insulin resistance (IR). NAFLD is 6 times more frequent in obese patients than in normal population. Up to 75% of patients with obesity have some degree of fatty deposits in the liver, which can reach 100% when these patients present morbid obesity.

The prevalence of NAFLD has risen in the last decades, similarly to obesity and type 2 diabetes mellitus (T2D), becoming the most common chronic liver disease worldwide. NAFLD has a reported prevalence of 10 to 46% in Europe and in the United States, while the median prevalence reported worldwide is around 20%. The treatment of NAFLD is based on weight loss through lifestyle modifications, pharmacologic therapy and bariatric surgery. Bariatric surgery does not only contribute to weight loss, but it also improves the comorbidities associated to obesity, such as T2D and pathological liver histological changes like hepatic inflammation and fibrosis.

DEFINITION OF NAFLD AND NASH

NAFLD is defined as an excessive fatty deposit in the hepatocytes in the absence of alcohol intake and of other known causes of fatty liver. NAFLD ranges from simple steatosis to non-alcoholic steatohepatitis (NASH) and even cirrhosis.

NAFL (non-alcoholic fatty liver) hepatic steatosis is present without evidence of significant inflammation, with > 5% of hepatocytes infiltrated with fat. This deposit of fat in the hepatic parenchyma is pathological when it exceeds 5% of the weight of the liver and other viral or metabolic liver diseases and the consumption of alcohol have been ruled out.

In *NASH* (non-alcoholic steatohepatitis) hepatic steatosis is associated with hepatic inflammation that may be histologically indistinguishable from alcoholic steatohepatitis. This condition will be determinant for the development of liver fibrosis and cancer.

Approximately 10 - 25% of patients with NAFLD will develop NASH, and 5 - 8% of those will develop liver cirrhosis within 5 years. After alcoholism and viral infections, NAFLD is the third main cause of liver cirrhosis.

ETIOLOGY

Hepatic steatosis is caused by the excessive accumulation of toxic lipids in the liver, including triglycerides, free fatty acids (FFA), ceramides and free cholesterol. This accumulation can result from the excessive importation of FFA from adipose tissue, from diminished hepatic export of FFA or from impaired beta-oxidation of FFA.

Although NAFLD has been considered the hepatic manifestation of the metabolic syndrome, new researches have shown that the association between NAFLD and metabolic syndrome is bidirectional. Insulin resistance (IR) and chronic inflammation are primarily responsible for these two entities.

The most important mechanisms in hepatic steatosis involve increased visceral adipose tissue, secretion of proinflammatory cytokines and adipokines and release of FFA into the portal system and systemic circulation, causing dyslipidemia and systemic IR. Therefore, IR, dyslipidemia and T2D could play a role in the etiopathogenesis of this entity. Given the importance of visceral adipose tissue, surveillance for patients with NAFLD should take into account an indicator of visceral obesity, and not only rely on BMI. Increases in visceral adipose tissue and intrahepatic fat correlate with increased gluconeogenesis, increased FFA levels and IR. Visceral fat is also associated with liver inflammation and fibrosis in patients with NASH, irrespective of IR, possibly through the mediation of interleukin-6 (a proinflammatory cytokine).

The main pathogenic factor related to steatosis is the increased flow and hepatic uptake of non-esterified fatty acids from excessive peripheral lipolysis, as a consequence of peripheral IR. Research has proved that adipose tissue (especially visceral adipose tissue) is subject to a state of chronic inflammation, with the ability to secrete adipokines. This fact has allowed to relate hepatic inflammation and the metabolic disorders that lead to the accumulation of triglycerides. NAFLD may also be present together with some endocrine diseases, such as polycystic ovary syndrome, hypothyroidism, growth hormone deficiency or hypercortisolism.

CLINICAL FEATURES

NAFLD usually occurs between the fourth and sixth decade of life. Most patients are clinically asymptomatic, although some of them may complain of fatigue, dyspepsia, and vague right upper abdominal discomfort. Regarding physical findings, some patients may have hepatomegaly due to fatty infiltration of the liver, but this is not a common finding and it might be related to patients with more advanced disease. We could also find stigmata of chronic liver disease in patients who have developed cirrhosis.

DIAGNOSIS

The diagnosis of NAFLD requires to rule out any history of alcohol abuse ($< 30\text{g/day}$ in men and $< 20\text{g/day}$ in women) and other causes of hepatic steatosis, such as hepatitis C virus infection, autoimmune hepatitis, Wilson's disease, medication use, starvation, parenteral nutrition, etc.

Methods for diagnosing NAFLD can be divided into non-invasive and invasive. Among the non-invasive we find laboratory tests and radiographic examinations. As for invasive methods, we refer mainly to liver biopsy, which is the gold standard for the diagnosis of NAFLD. Furthermore liver biopsy is the only method available to differentiate NAFL from NASH.

Most patients with NAFL or mild NASH are asymptomatic and NAFLD is detected accidentally in a routine analysis. Actually elevated liver enzymes are detected in approximately 20% of NAFLD patients.

Regarding *laboratory tests*, aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels can be normal or moderately elevated. Also an AST: ALT ratio < 1 supports the diagnosis of NASH. Besides liver enzymes, the following tests should also be obtained: anti-hepatitis C virus antibody, hepatitis A IgG, hepatitis B surface antigen, surface antibody and core antibody. We should also obtain iron levels, ferritin, and total iron binding capacity. Finally there is a series of parameters related to autoimmune hepatitis that should be assessed, such as serum gammaglobulin level or antinuclear body. However laboratory tests might be normal, and when they show any abnormality, they are not sufficient for making the diagnosis. In terms of *radiographic examinations*, ultrasound is the most available method and it represents the first-line diagnostic tool for detecting liver steatosis. It is a useful tool for diagnosing moderate to severe degree hepatic steatosis, but its accuracy is limited regarding mild steatosis. There are other methods that are also used, such as computed tomography (CT), magnetic resonance (MRI) and proton magnetic resonance spectroscopy (MRS). CT has limitations such as the fact that there is a potential risk related to its radiation and it has also a limited accuracy in detecting mild steatosis. MRI and MRS provide a highly accurate and reproducible diagnosis for evaluating NAFLD.

We must also take into account FibroScan, which is used to assess liver fibrosis by measuring liver stiffness.

Nevertheless, as non-invasive methods cannot make a distinction between simple steatosis and NASH, liver biopsy remains necessary, especially when radiographic examinations are not consistent with fatty infiltration, when other causes for steatosis have not been excluded or when the patient has signs or symptoms of cirrhosis.

As for *liver biopsy*, it remains the gold standard for the diagnosis of NAFLD and it represents the only method to confirm the diagnosis of NASH as well as for establishing the different stages of fibrosis. However it is only performed when the diagnosis remains unclear after obtaining laboratory tests and hepatic imaging, or if the information provided by the biopsy might condition the patient's treatment. The reason why this technique is so restrictively indicated is that it constitutes an invasive method with possible serious complications. In addition, histological alterations of the liver are not distributed homogeneously and the biopsy may be unrepresentative.

TREATMENT

Although the optimal treatment has yet to be elucidated, the treatment of NAFLD is focused on weight loss. For achieving this goal we count on three therapeutic weapons that can be complementary: lifestyle modifications, pharmacologic therapy and bariatric surgery. The main goal of these therapies is to slow down or stop the disease progression, whether it is in its earliest stages or in the stage of fibrosis or cirrhosis.

For the inflammatory parameters of the liver to improve, patients must lose at least 5% of their total weight. If weight loss exceeds 7%, NASH may be resolved. However, to reduce the degree of liver fibrosis, patients must lose at least 10% of their total weight.

The improvement of NAFLD is directly proportional to the weight loss, regardless of whether it has been achieved through lifestyle changes or bariatric surgery.

Lifestyle Modification

First line therapy for NAFLD includes lifestyle changes aimed at weight loss through low-calorie diets and physical exercise. Weight loss leads to a reduction in both visceral adipose tissue and IR. There are different publications that show a significant reduction of hepatic steatosis after the implantation of lifestyle changes, as well as an improvement in IR and BMI.

It is not clear what kind of exercise is the most beneficial, but it has been shown that adding physical exercise to a low-calorie diet can enhance the benefits in the management of NAFLD and IR, regardless of weight loss.

Pharmacologic Therapy

Nowadays there is not any drug specifically accepted for the treatment of NAFLD, with weight loss being the only treatment that has proved to be effective.

Metformin has beneficial effects in preventing diabetes onset and leads to mild weight loss. These two effects are also beneficial for NAFLD patients, although metformin has not proved to have a direct effect on liver histology.

Another pharmacologic option would be pioglitazone, which also helps in improving IR and histological hepatic disease activity. However, due to its side effects, its general application is not recommended.

Bariatric Surgery

In Europe and North America, the prevalence of NAFLD among patients whose BMI overcomes 40Kg/m² ranges between 75% and 100%. However, NAFLD alone does not constitute an indication for bariatric surgery at the moment.

Weight loss, regardless the way it is achieved, is the most important factor related to the improvement in the histological characteristics of patients with NAFLD. In fact, this improvement is directly proportional to the weight lost. In this regard, bariatric surgery allows the patient to achieve a greater and sustained weight loss over time. In addition, the main etiologic factors involved in the development of NAFLD are obesity and IR, and there is scientific evidence that bariatric surgery is effective both for weight loss and for the resolution of diabetes mellitus type 2.

As for the most recommended bariatric surgery technique, sleeve gastrectomy and gastrointestinal bypass techniques have proved to be superior to gastric banding in terms of weight loss.

It is important to take into account the stage of liver disease in obese patients with NAFLD undergoing bariatric surgery, since liver cirrhosis is associated with increased postoperative morbidity and mortality. Furthermore it is also important to bear in mind that

the mortality of these patients decreases as the experience of both the medical and surgical team increases.

In the case of obese patients with NAFLD presenting Child-Pugh class A liver cirrhosis without portal hypertension or decompensation, both sleeve gastrectomy and gastrointestinal bypass are recommended. However, it should be borne in mind that some publications describe that gastrointestinal bypass techniques can lead to the massive destruction of adipocytes and an important increase in the levels of free fatty acids that are taken up by the liver, which results in worsening of steatosis, steatohepatitis, or even cirrhosis.

Fortunately this complication was rather related to more aggressive techniques that are no longer performed as the jejunoileal bypass procedure, and it is exceptional to find it after the completion of a Roux-en-Y gastric bypass (RYGB), which is the most common derivative technique today. Nevertheless, since sleeve gastrectomy (SG) does not have a derivative component, it is considered to be more physiological and has less risk of hepatic decompensation both during the immediate postoperative period and during the weight loss that takes place after surgery.

It also allows endoscopic access to the gastric sleeve and duodenum, which may be important depending on the evolution of the hepatopathy of these patients.

Therefore, in obese patients who have developed cirrhosis, surgical treatment will be conditioned by the stage of liver disease presented by the patient, which will be measured using the Child-Pugh scale or the MELD-Score. We must bear in mind that patients with decompensated cirrhosis should not undergo bariatric surgery given the high risk of potentially serious and even fatal complications.

Bariatric surgery using mixed procedures (restrictive and malabsorptive) as a Roux-en-Y gastric bypass, improves liver abnormalities associated with non alcoholic fatty liver disease in morbidly obese patients.

Kalinowski et al. studied the evolution of NAFLD and NASH using intraoperative liver biopsies in patients who underwent bariatric surgery (SG vs RYGB). Patients who underwent SG showed significant improvements in AST, ALT, and gamma-glutamyltransferase at 12 months which revealed a greater improvement in liver abnormalities and inflammation for SG.

Praveen Raj and coworkers showed a greater improvement of steatosis, lobular inflammation, ballooning degeneration and fibrosis among patients with NAFLD who underwent a sleeve gastrectomy in comparison to a Roux-en-Y gastric bypass.

CONCLUSION

We can conclude that it is important to analyze through further studies the benefit of bariatric surgery in patients with NAFLD and high risk of developing cirrhosis, given the existing evidence that these techniques improve both liver steatosis and fibrosis, besides contributing to weight loss and the improvement of insulin resistance.

Chapter 305

FATTY LIVER DEVELOPMENT: IMBALANCE BETWEEN ACQUISITION AND REMOVAL OF LIPIDS

Lorea Zubiaga*, MD, PhD

Lille University, Inserm-U1190, EGID, CHU Lille, Lille, France

ABSTRACT

Fatty liver, hepatic steatosis and Nonalcoholic fatty liver disease (NAFLD) is an umbrella of terms used to describe a range of related disorders characterized by the deposition of triglycerides as droplets in the cytoplasm of hepatocytes. The fatty liver is now considered a multifaceted complex systemic condition. Moreover, recent evidence suggests that this steatosis may progress to an advanced liver fibrosis challenging the previous dogma that “*steatosis is a benign condition*”. High levels of insulin and insulin resistance are often associated with hepatic steatosis and although it is necessary, is not sufficient for the disease debut and progress. NAFLD, obesity, Type 2 Diabetes and Metabolic syndrome are linked by a vicious circle which induce several difficulties in the metabolic control and where bariatric and metabolic surgery has changed many paradigms.

Keywords: fatty liver, western diet, *de novo* lipogenesis, fatty acids, very low density lipoprotein, insulin resistance

INTRODUCTION

Fatty liver is the most frequent chronic hepatic disease in developed countries and its prevalence runs in parallels the rise in obesity, type 2 diabetes (T2D) and metabolic syndrome (MetS). This disease is associated to the modern life and its most common interpretation is related to over-nutrition and consumption of well-known western diet [1]. However, the fatty

* Corresponding Author's Email: loreazubiaga@gmail.com.

liver can also be induced by endocrine disorders, viral infections or side effects of pharmacological therapies. In most cases it is an ailment that causes no symptoms and it moves silently generating tissue damage to liver parenchyma, which can lead to fibrosis as NASH, then cirrhosis and finally the liver failure [2].

Fatty liver begins with the aberrant accumulation of triglycerides (TG) in the liver. The pathogenesis of this disease remains poorly understood and its evolution of the liver steatosis is directly interconnected to classic components of the metabolic syndrome as: hyperglycemia, hyper-insulinemia, insulin resistance and hypertriglyceridemia [3]. However, most of the patients with fatty liver display all of these conditions independent of body weight [4]. In fact, the “lean NAFLD” phenotype has a renewed interest among researchers. This fact is due to that this condition developments selectively increase in visceral adiposity without changes in the body mass index and, sometimes, even with normal waist circumference [5]. This “lean NAFLD” patient develops metabolic problems and cardiovascular disease similarly to obese patients and this is a worrisome problem, because these patients are difficult to diagnose and even more difficult to treat [6]. However, the “lean NAFLD” allow us to study the genetic component of this disease. A recent publication confirms that the fatty liver development and progression derive from a complex interplay between genetic and environmental factor [7], and we should probably distinguish a strong genetic component of the disease from the metabolic origin as such as in the diabetes (type 1 diabetes/MODY/T2D) [8]. However, in this assessment we will focus on the physiopathology hypotheses of this disease that are closer to obesity, concentrating the concepts on the damage associated with environmental rather than genetic causes and without entering the complex world of inflammatory and immunological signals that also accompany this disease.

ASSUMPTIONS AND DATA

Fatty Acids as a Regular Fuel for Energy

As a central regulator of lipid homeostasis, the liver is responsible for directing the synthesis of new fatty acids, their export and subsequent redistribution to other tissues, as well as their utilization as energy substrates [9]. Nearly all forms of fatty acids have an even number of carbon atoms and they can be presented as individual fatty acids or free fatty acids (FFA) and also as non-esterified fatty acids (NEFA) [10]. Fatty acids are the foremost metabolic fuel in the body and they play a central role providing energy to the majority of tissues (except brain, which use glucose) particularly during fasting. Circulating FFA are reabsorbed in various organs where, if not oxidized, they accumulate as intra-cytoplasmic droplets of TG or like some lipid intermediates, such as the diacyl-glycerols (DAG), molecules which, sometimes can promote cell lipotoxicity [11]. In the liver, the major storage form of FFA is in triglycerides (TG) shape. The selection of TG as energy resource in the body comes from two physicochemical properties: TG provides greater caloric density (9 kcal/g) than other substrates (4 kcal/g from carbohydrates or proteins) and they can accumulate to high levels in the cell with no adverse osmotic or colloidal effects. However, the lipids accumulation on the liver is defined as the deposition of TG as droplets in the cytoplasm of hepatocytes in more that 5% of these cells [12].

Buildup of Lipids in the Liver Is a Normal Response to Fasting

Hepatic lipid accumulation occurs transiently as a metabolic adaptation to continuous food deprivation (fasting or starvation). In humans, this period normally corresponds to 12–24 h without food intake [13]. In the first phase of fasting, the hepatic glucose output is derived both from gluconeogenesis and glycogenolysis. Both processes entail a reduction of glycogen stores in the liver. However, if an extra demand of energy occurs during this period, hormonal signals stimulate adipose tissue to release NEFA into circulation to address to the liver where they will be used as energy substrates. Within a prolonged period of fasting the reduction of hepatic glycogen stores further stimulates adipose tissue lipolysis. This feedback is essential to maintain a constant supply of energy to the body [9]. During this process the liver upregulates expression of the hepatic fatty acid transporter. Fatty acids in the liver act as main substrate for the oxidative process and to generate ketones. In this way, the liver maintains two mechanisms that prevent the oxidation of amino acids in the hepatic parenchyma. Avoiding oxidation of amino acids is essential for normal functions in the cells. During a period of starvation (fasting periods prolonged for more than 60 hours) the accumulation of hepatic lipids is higher but also begins the second phase of the liver as an energy provider through the transformation of those lipids into molecules that can travel to other organs and make up for the energy deficit (as ketone bodies and lipoproteins) [14]. In this sense, the lipid stockpiling in the liver and the transformation of them in energy seems to be a protective mechanism to all body when food intake is compromised [13].

Figure 1. Lipid metabolism in the liver.. Processes that increase the entry of fatty acids and triglycerides or reduce their exit can cause hepatic steatosis. The main sources of FFA are: diet, endogenous synthesis and lipolysis in peripheral tissues. Carbohydrate intake increases glucose and insulin levels, which activate two transcription factors (ChREBP and SREBP-1c) in the liver that promote de novo lipogenesis (DNL). FFAs have several possible destinations within the hepatic parenchyma: 1) Esterified by adipose triglyceride lipase (ATGL) and stored as triglycerides (TG) in lipid droplets. 2) Metabolized by oxidation processes (B-ox or W-ox) forming substrates for a new synthesis (Acetyl-CoA) and also as reactive oxygen species (ROS). They can also form ketone bodies that are expelled into the circulation. 3) Packed with apoB100 by means of Microsomal triglyceride transfer protein (MTTP) and segregated in the blood as low-density lipoproteins (VLDL).

The mechanisms that promote the liver fat piling up are not fully elucidated but it has been hypothesized that when the fatty acids acquisitions exceeds the capacity for removal them, these fatty acids are over-stored. The fatty acids used for hepatic TG formation are derived from three sources: (1) diet, (2) De Novo synthesis, and from (3) the adipose tissue. In the other side, fatty acids that arrives to the liver parenchyma have three major destinations: (a) They can be oxidized to produce energy and ketone bodies, (b) re-esterified to TG and stored in droplets, or (c) coupled to apolipoproteins and secreted as very-low-density lipoproteins (VLDL) [15]. An overview of each of these processes is described in Figure 1 and will be described below.

Fatty Liver and Diet

The increasing prevalence of fatty liver the increased in the general population over the past 40 years is due to changes in the quantity and composition of food. Specifically, has been attributed to the widespread availability of the so-called western diet that is rich in saturated fats and refined sugars [16]. The western diet (WD) is mainly described as a high-fat/high-sugar diet or specifically as high-cholesterol/sucrose (fructose) diet. Regardless of the combination of the elements that define the WD, what is relevant in this nutritional form is the fact that this diet promotes hepatic steatosis in conjunction with altered liver transcriptomic and metabolomic profiles. These altered profiles completely modify the signals that control liver functions, inducing phenomena that can be paradoxical. For example, giving the order to increase the internal storages when in reality there is already an excess of fats [1].

Analyzing in detail the effect of the WD it has described the influence of hypercaloric diets on fatty liver. Indeed, when talking about high-calorie diets, it is easy to understand diets rich in saturated fatty acids (SFA). However, the studies analyzing the hypercaloric point of view usually have been undertaken using different degrees of energy excess and the macronutrient of interest are the carbohydrates [2]. In fact, some of these studies have demonstrated that an acute consumption of a high-fructose diet leads to a significant increase in liver fat content [17]. The most plausible hypothesis for this phenomenon is that fructose consumption routes dietary carbons directly to the liver in a promptly manner to enter biosynthetic pathways, including De Novo lipogenesis (DNL) [18]. The way in which this process predisposes to fat accumulation will be described later in the reading. Nonetheless, when comparing hypercaloric diets enriched in either fructose or glucose it would appear that both influence liver fat accumulation in a similar manner [19]. The majority of carbohydrates in the WD coming from added extrinsic sugars (Ex. sucrose and corn syrup). The added sugars universally present in modern food are added to enhance the taste in some beverages and processed food and they are consumed unnoticed manner. Both sucrose and corn syrup are composed of approximately 50/50 proportion of fructose/glucose and these two sugars consumed in combination are more deleterious and more inclined to stimulates DNL than when they are taken isolated [20].

On the other hand, faced with the same amount of calories, the predominant effect is the composition of macronutrients in the diet. Thus, a diet composed mainly of SFA will be more harmful even if it has a lower calorie intake [2]. Diets rich in SFA cause an increase in the accumulation of hepatic TG, while diets rich in monounsaturated fatty acids (MUFA) or

polyunsaturated fatty acids (PUFA) tend to decrease the TG in the liver. The mechanism by which the SFA lead to an accumulation of TG is not yet clarified, although it has been suggested that the lipotoxicity of this kind of fat alters per se the oxidative stress of the cell (at the endoplasmic reticulum level and/or mitochondrial) [21]. There are also hypotheses that point to a disordered metabolism of phospholipids [22] or to alterations in the regulation of lipogenic genes, which promote the production and accumulation of TG. In general, all of these ideas pose a disturbance of liver to handle a high flow of lipids from the diets. As these lipids cannot enter the oxidation or lipoprotein production pathways, they accumulate in the parenchyma [11]. Supporting this idea, Koopman et al. reported that the accumulation of fat in the liver was noticeably greater when the same amount of calories were consumed in a greater number of intakes during the day; i.e., isocaloric high fat diets taken 5 times a day (meals + snacks) were more harmful than taken 3 times (meals) a day [23]. Therefore, in the development of fatty liver not only the number of calories is important, but also how they are distributed in relation to the composition of macronutrients, as well as the frequency with which these calories are ingested during the day.

Adipose Tissue Lipolysis and Hepatic Lipid Uptake

When energy demand exceeds metabolic energy from diet, NEFAs are mobilized from white adipose tissue (WAT) by the lipolysis. Lipolysis process is stimulated by the catecholamines while the insulin is the key signal to inhibit it. During fasting and intense exercise, insulin levels are low, allowing norepinephrine, cortisol and growth hormone to synergistically stimulate lipolysis from the WAT, allowing an increase of circulating fatty acid availability [24]. Hormonally regulated lipolysis depends on the activity of the lipolytic enzyme, hormone-sensitive lipase (HSL). Insulin and catecholamines from sympathetic nervous system (SNS) modulate HSL activity by decreasing and increasing respectively the energetic signals coming from the adipocytes. SNS activity also stimulates cortisol release. The metabolic response of WAT to corticoids also depends on the duration of exposure, where chronic stimulation induces the lipolysis by transcriptionally regulation of HSL [25]. Excessive lipolysis and adipose tissue fatty acid release into circulation results in ectopic accumulation of lipids as liver and the vascular system.

In obesity, as in fasting periods, there is a rise in sympathetic activity and adipose tissue lipolysis [26]. This increased lipolytic response is associated to the excess of the adiposity, characterized by a decreased lipolytic capacity in subcutaneous adipose tissue and an increased lipolysis from VAT [27]. In subcutaneous adipose tissue, obesity decreases HSL expression, limiting sensitivity to adrenergic stimulation. However, in obesity there is an increase of sensitivity to catecholamine-induced lipolysis in the visceral fat so, catecholamine-stimulated lipolysis depends on the regional adipose tissue depot. The reduction of the lipolytic hormone expression along with increased adipose tissue mass results in more adipose-tissue-derived fatty acids entering circulation in obese than in normal-weight individuals [28]. Moreover, in obesity the clearance by skeletal muscle is decreased. This phenomenon allows the increased lipolysis in the adipose tissue results in hyperlipidemia and an increased hepatic lipid uptake, which, is critical for the development of hepatic TG accumulation [29].

De novo Lipogenesis

Hepatic *De novo* lipogenesis (DNL) is the biochemical process of fatty acids synthesis from acetyl-CoA subunits coming from different pathways, most commonly from glycolysis and carbohydrate catabolism [30]. The DNL is driven by two transcription factors that are widely expressed in the liver and in the adipose tissue: the Sterol Response Element Binding Protein 1c (SREBP1c) and the Carbohydrate Response Element Binding Protein (ChREBP). Both factors regulate expression of key lipogenic genes to produce the fatty-acid synthase and the acetyl-CoA carboxylase, the two key enzymes of DNL. These enzymes use the acetyl-CoA and the malonyl-CoA derived from glucose catabolism (or other carbon precursors) to generate palmitate [31]. Usually, the palmitate has detrimental effects in the body; however, the palmitate synthesized by DNL, can be modified by endogenous enzymes to produce multiple lipid species that are easily to storage [32].

Under normal physiological conditions, an increase of circulating glucose is followed by a rise in lipogenic enzyme expression, which stimulates hepatic glucose clearance and storage of the carbons as fatty acids and TG. Carbohydrates en general and specially glucose regulate directly the ChREBP activity. In the same sense, postprandial hyperglycemia leads to increase circulating insulin and this hormone stimulates SREBP1c in the liver. Thus, the hyperglycemic and hyperinsulinemic conditions are closely linked to DLN. In addition, SREBP1c indirectly contributes to the development of hepatic insulin resistance, since enhanced lipogenesis and subsequent accumulation of harmful lipid species, such as DAG, which in turn may interfere with insulin signaling [11].

While glucose is the main substrate for DNL, fructose is a highly lipogenic substrate which can provides an extended number of carbons. The importance of fructose as a lipogenic substrate comes from the main function of the liver in fructose clearance. In the first pass of portal circulation after meal ingestion, the liver sequesters 71% of dietary fructose, while only takes 13% of glucose [33]. Moreover, fructose is phosphorylated at carbon 1 rather than carbon 6, so it cannot be used to synthesize glycogen but instead is quantitatively converted to glyceraldehyde-3-phosphate, providing the main substrate for DLN. Similarly, fructose may bypass the critical regulatory step catalyzed by phosphofructokinase-1 in glycolysis [34] so it can enter directly to biosynthesis reactions. Even more, fructose also potentiates glucose-stimulated insulin secretion and also increases the activation of ChREBP. In this way, a diet rich in fructose increases ChREBP binding to DNA nearly four fold [35]. This has implications that mean fructose may reinforce some of the pathogenic mechanisms leading to fatty liver via DLN.

Another pathway associated with DLN is mediated by excess in glucocorticoids. The 11 β -hydroxysteroid dehydrogenase type 1 (11 β -HSD1) is a key enzyme that catalyzes the intracellular conversion of cortisone to physiologically active cortisol and it is an NADPH-dependent enzyme highly expressed in key metabolic tissues as the liver and the adipose tissue. The expression of this enzyme is up-regulated in obesity leading to an excess of glucocorticoid production cortisol overproduction from adipose tissue is an important stimulus for the liver's lipogenic pathways, however local liver cortisol production is much more active to stimulate the fatty acids production. In fat, corticoids contribute to driving hepatic steatosis by decreasing lipid oxidation and increasing DNL and TG esterification [13].

Fatty Acids Oxidation and Ketogenesis

Oxidation of fatty acids occurs principally in the mitochondria, providing a source of energy to generate ATP especially when circulating glucose levels are low. During this process, fatty acid chains are broken apart into acetic acid fragments and generates acetyl-CoA molecules that are further oxidized by the citric acid cycle (TCA/Krebs cycle) to produce carbon dioxide and water and release energy. This process is traditionally called Beta-oxidation (β -ox). β -ox is primarily facilitated by the hepatocytes mitochondria due the action of the mitochondrial tri-functional protein (MTP), an enzyme that catalyzes the last 3 steps of this process [36]. Hepatic β -ox in response to lipid accumulation prevents lipotoxicity and providing extra energy when in periods of starvation, the gluconeogenesis is insufficient. In this sense, limiting β -ox process is usually associated to a severe exacerbation of hepatic lipid accumulation [37].

However, the oxidation also can be developed in the cytoplasm by the peroxisomes (β -ox) or cytochromes (ω -ox). These two last settings usually are activated due to mitochondria lack the ability to oxidize very long chain fatty acids or when exists environments with lipid overload. However, these two processes generate considerable amounts of reactive oxygen species (ROS), oxidative stress, and toxic dicarboxylic acids, potentially promoting inflammation and hepatic damage [15]. Indeed, lipid oxidation by these pathways can produce a damage into mitochondrial DNA further diminish mitochondrial function, establishing a self-perpetuating vicious cycle to exacerbate mitochondrial dysfunction and oxidative stress [38].

DNL is usually responsible for the steatosis resulting from high-fructose diets. However, fructose can also promotes the inhibition of β -ox via carnitine palmitoyltransferase I (CPT1) activity inhibition. This enzyme regulates the formation of acyl-carnitines by catalyzing the transfer of the acyl group of a long-chain fatty acyl-CoA from coenzyme A to l-carnitine. The resulting product is often Palmitoylcarnitine the first committed intermediate produced during fatty acid synthesis. But, inhibition of CPT1 resulting increases malonyl-CoA synthesis and chronically downregulates the expression of beta-oxidative genes [13]. One again, the hepatic lipid accumulation resulting from dietary fructose also affects another process, which is key in the lipids distribution.

β -ox is upregulated in the post-absorptive state and reduced in the postprandial state, a response mediated by systemic substrate and hormone concentrations. For example, the glucagon stimulates β -ox by upregulation of peroxisome proliferator-activated receptor α (PPAR α) activity, while insulin and glucose downregulates β -ox by suppressing adipose tissue TG lipolysis, reducing the delivery of fatty acids to the liver and increasing hepatic DNL [11]. Thus, obesity can causes a decrease in beta-oxidation, which contributes to lipid accumulation [38].

Ketogenesis is the catabolic process for ketone bodies production through breakdown of fatty acids. This process supplies energy under circumstances such as fasting or caloric restriction to certain organs, particularly the brain, heart and skeletal muscle. This event is notably important when the gluconeogenesis process is insufficient and can cause hypoglycemia. As energy requirements are urgent the liver oxidizes fats and manufactures ketone bodies [39]. Ketogenesis occurs constantly in a compensatory amount in healthy individuals but it can also take place when there is insufficient insulin (Ex. in type 1 diabetes), particularly during periods of “ketogenic stress”. In these cases, pushing the body to

chronically supply itself with energy from ketone bodies can create a lethal condition called ketoacidosis. Fatty acids are enzymatically broken down in β -ox to form acetyl-CoA. However, if the amounts of acetyl-CoA generated in this process overwhelm the capacity of the TCA cycle, acetyl-CoA is then used instead in biosynthesis of ketone bodies. Hepatic ketogenesis could potentially contribute to control and avoid fatty liver pathogenesis, because it is activated in states of FFA circulation and diminished carbohydrate availability concentrations are very low. But, in obesity the raised FFA levels exceed the ketogenic machinery as various substrates and enzymes from this process cannot be recycled at the same rate as they are consumed. On the other hand, hyperglycemia acts as inhibitor of ketogenesis. In both pathways, the decrease of ketone bodies production rate allows the lipids accumulation in the liver [37].

Liver Lipoprotein Management

A central metabolic role of the liver is to maintain plasma glucose within narrow physiological limits regardless of the nutritional state of the animal. In energy excess, glucose is converted to fatty acids, which are further used to synthesize TG. Hepatic TG derives from: 1) uptake of circulating fatty acids; 2) uptake of circulating remnants of VLDL and chylomicron (lipase action); and 3) through the hepatic DNL TG can be stored or incorporated into very-low-density lipoproteins (VLDL) and secreted into the blood. VLDL synthesis by the liver involves complex processes such as synthesis and the coordinated assembly of protein components (apolipoproteins) and of hydrophilic (phospholipids, free cholesterol) and hydrophobic (triacylglycerols (TAG), cholesteryl esters) lipid components. VLDL particles are formed in the endoplasmic reticulum, where apolipoprotein B100 (apoB100) is lipidated in a process catalyzed by the enzyme microsomal triglyceride transfer protein (MTTP) [40]. Consequently, apoB100 and MTTP are key elements in hepatic VLDL secretion and in maintaining hepatic lipid homeostasis and some genetic defect in one of these 2 elements is associated with the presence of fatty liver. The production and transport of the VLDL is an efficient source of energy either for storage in adipose tissue or for its utilization by muscles [41].

The precise mechanisms responsible for the close relationship between fatty liver and obesity are still unknown, but is evident to think that if exist a blockade of hepatic VLDL production and secretion, this situation results in an accumulation of TG in the liver favoring the development of fatty liver. However, other hypotheses have been proposed with the insulin in the target. Postprandial insulin can suppress hepatic VLDL production by a number of mechanisms, including the down-regulation of the MTTP gene expression, increasing degradation of apoB within hepatocytes and inhibiting the maturation of VLDL. However, the suppressive effect of insulin on VLDL production is reversed in chronic hyperinsulinemia conditions. In addition, it has been reported that high levels of insulin plus insulin-resistance do not decrease the production of the VLDL, but instead they stimulated it [42] as in obesity, T2D and MetS. In this sense, the IR of adipose tissue leads to higher circulating NEFA concentrations, and an increased FFA flux to the liver stimulating hepatic TG synthesis so, lipids storages increase in a first stage of fatty liver. The excess of lipids in the liver parenchyma also impairs hepatic extraction of insulin. Hepatic insulin resistance is also linked to an increasing TG synthesis and VLDL production and secretion as VLDL-TG.

Despite higher VLDL-TG secretion in patients with fatty liver, regular VLDL-apoB100 secretion did not change, suggesting that hepatic steatosis patients do not secrete additional, but instead larger and more TG-rich, VLDL particles. Nevertheless, enormous VLDL particles cannot be secreted when they have a diameter that exceeds that of the sinusoidal endothelial pores [11]. This situation can be another cause for lipids accumulation in the liver parenchyma.

Glucoregulatory Hormones

Insulin

Most patients with fatty liver have hyperinsulinemia and IR at the same time, leaving to glimpse that insulin seems to be associated in several disturbances in the called metabolic diseases [43]. In fact, postprandial hyperinsulinemia is present in 100% of NAFLD individuals and usually is independent of diabetes status [44]. Insulin promotes the DNL and glycerol-neogenesis, both pathways are raised in steatosis, even in non-diabetic patients, contributing to the synthesis of hepatic TG and the promotion of fatty liver. In NAFLD patients the IR promotes the activation of hepatic stellate cells, which are the trigger that initiates the fibrogenesis process that characterize NASH [45]. In the same manner, hepatic synthesis of palmitate (via DNL stimulated by insulin) can cause increases the risk of lipotoxicity and cell damage. Moreover, hyperinsulinemia and IR are considered better predictors of hepatic injury than visceral adiposity [46]. Therefore, insulin high levels and IR conditions are linked with abnormal concentration of lipoproteins, elevated VLDL production, high levels of plasmatic cholesterol, TG and LDL that allows to cardiovascular diseases.

Glucagon

Glucagon function is opposite that of insulin since glucagon stimulates glucose production via activation of hepatic glycogenolysis and gluconeogenesis by glycolysis inhibition. It also regulates fatty acid metabolism via stimulation of peripheral lipolysis, reduction of malonyl-CoA and stimulation of fatty acid oxidation. Elevated plasma concentrations of glucagon have been reported in patients with cirrhosis, chronic hepatitis and fatty liver disease. In this last group, fasting high levels of glucagon were reported whether or not the patients were diabetic [47]. This evidence has suggested that hyperglucagonemia may have originated from a liver-steatosis rather than a pancreatic compensatory signals in the T2D evolution. As in the case of insulin, know if exists a previous hormone-resistance in the tissues, or if the resistance is due to hormonal overstimulation is still the dilemma. However, it was proposed that the level of liver TG may be involved in the mechanism of HF diet-induced glucagon resistance in the liver. This suggestion is supported the TG levels correlated inversely proportional to the glucagon-stimulated hepatic glucose production. Impairment in the expression of glucagon receptors it has been also linked to the liver fat content [48].

CONCLUSION

A balance between lipid acquisition and disposal establishes intrahepatic fat levels. In general, it has been reported that liver acquires lipids through the uptake of circulating fatty acids (from the diet or adipose tissue lipolysis) and via DNL. Conversely, lipids may be consumed through beta-oxidation ketogenesis and through export VLDL particles. Regarding this, it is possible guess why bariatric surgery is useful in the manage of the fatty liver, since the vast majority of techniques reduces hepatic fat acquisition pathways and regulates IR, common factor in this metabolic disorders.

Chapter 306

HISTOPATHOLOGY OF NAFLD AND NASH

Soledad García-Gómez-Heras*

Human Histology and Pathology, Health Science Department,
Rey Juan Carlos University, Madrid, Spain

ABSTRACT

The histopathological features of adult NAFLD/NASH are: hepatocellular steatosis, hepatocellular ballooning, inflammatory infiltrate, fibrosis, glycogenated nuclei, apoptotic hepatocytes, Mallory-Denk Bodies (MDBs), iron deposition, megamitochondria and ductular reaction. The necessary components for the diagnosis of NASH are: steatosis (accentuated in zone 3), lobular inflammation (mixed, mild) and hepatocellular ballooning (most apparent near steatotic liver cells, typically in zone 3). Fibrosis is not necessary for the diagnosis of NASH, although it is usually present.

There are different histopathological scoring systems and all have both pros and cons. The methods currently used to semi-quantitatively evaluate the histological lesions of NAFLD are: the NAFLD Activity Score (NAS) and Fibrosis Score by the NASH Clinical Research Network (NASH-CRN) and the 'Fatty Liver Inhibition of Progression (FLIP)' Algorithm and Steatosis, Activity, and Fibrosis (SAF) Score. These ideas will be, discussed in this chapter.

Keywords: histopathology, NASH, hepatocellular-Steatosis, Mallory-Denk bodies, steatohepatic hepatocellular carcinoma, liver fibrosis

HISTOPATHOLOGICAL LESIONS IN THE LIVER

From a morphological point of view, the liver is an organ with a limited repertoire of responses against aggression. Regardless of the cause, five types of response can be observed.

* Corresponding Author's Email: soledad.garcia@urjc.es.

1. Inflammation

The hepatocyte lesion associated with the arrival of acute or chronic inflammatory cells to the liver is called hepatitis. The attack to liver cells expressing viable antigens by sensitized T lymphocytes is a frequent cause for the hepatic lesion. Inflammation may be limited to the lymphocytes' point of entry (portal spaces) or spread to the rest of parenchyma.

Although hepatocyte necrosis can precede inflammation, it can also be the other way around. When hepatocytes experience necrosis or apoptosis, the macrophages in charge of withdrawing the remainders quickly phagocytize the dead cells and generate groups of inflammatory cells in an otherwise normal parenchyma. Foreign bodies, microorganisms, and different drugs can trigger these granulomatous-type reactions.

2. Degeneration

Alterations that are secondary to toxic or immune aggressions can make hepatocytes adopt a swollen and edematous aspect, ballooning degeneration), with irregular blots in the cytoplasm and huge empty spaces.

Another possibility is when the biliar material retained confers a swollen and diffuse spongy appearance to hepatocytes, vacuolar degeneration.

In viable hepatocytes, different types of substances (like iron, copper, fat or retained biliar material) can accumulate. The concentration of fat droplets inside hepatocytes is called steatosis. When they are multiple tiny droplets that do not displace the nucleus, this is called microvacuolar steatosis, typical of acute alcoholic liver disease, Reye syndrome, and acute hepatic steatosis of pregnancy.

In livers of obese or diabetic patients, a single huge vacuole can be found. It is able to displace the nucleus. This lesion constitutes macrovacuolar steatosis.

3. Cell Death

Any important aggression to the liver can cause hepatocyte destruction.

When cell death is caused by immune or toxic mechanisms, it takes place through apoptosis, in which isolated hepatocytes retract, show pyknosis, and acquire an intensely eosinophilic aspect. Other hepatocytes may swell osmotically and break, in the so-called hydropic degeneration or lithic necrosis.

In the case of necrosis, liver cells appear a bit stained and mummified with a greater frequency due to ischemia (coagulative necrosis).

In the context of ischemia and various pharmacologic and toxic reactions, hepatocellular necrosis is distributed throughout the regions surrounding central veins (centrolobulillar necrosis). Mediozonal or pure periportal necrosis are rare.

In the most severe toxic or inflammatory lesions, apoptosis or necrosis of contiguous hepatocytes may comprehend adjacent lobules following a porto-portal pattern, porto-central pattern, or centro-central pattern (bridging necrosis).

Necroses in whole lobules (submassive necrosis) or in most part of liver parenchyma (massive necrosis) normally cause liver failure.

4. Fibrosis

Tissue generates fibrous tissue as a response to inflammation or to a direct toxic aggression.

This collagen deposit has everlasting consequences for hepatocyte irrigation and perfusion patterns. In the first stages, fibrosis arises in the interior or around porta spaces or central veins, or deposits directly in sinusoids. Over time, fibrous bands end up joining liver regions (porto-portal, porto-central or centro-central). This process is called bridging fibrosis.

Unlike other lesions that are reversible, fibrosis normally is an irreversible consequence of liver lesions. However, under certain circumstances, fibrosis has shown to decrease when the liver lesion has stopped. The best known cases of fibrosis regression are hepatic schistosomiasis infection and hereditary hemochromatosis.

5. Cirrhosis

When fibrosis and parenchymal lesions are maintained, the liver will end up subdivided into nodules of hepatocytes in regeneration, surrounded by scar tissue, and this is called cirrhosis.

It is one of the main causes of death in the Western world. Regardless of etiology, end-stage cirrhosis is characterized by:

- fibrous walls, in the form of delicate bands or wide scars replacing several adjacent lobules.
- parenchymal nodules, caused by the regeneration of hepatocytes that were isolated, of a size ranging from small (less than 3 mm diameter or micronodules) and large (up to several cm diameter or macronodules).
- alteration of the whole liver architecture.

Cirrhosis pathogenesis. The three main anatomopathological mechanisms that combine to produce cirrhosis are hepatocellular death, regeneration, and progressive fibrosis.

Regarding fibrosis, an element to consider is that the normal liver contains types I, III, and IV interstitial collagen. It concentrates in porta spaces and around centrilobulillar veins, with occasional bands in the parenchyma. A delicate reticular grid of IV collagen is arranged in the space between endothelial cells in the sinusoids and hepatocytes (space of Disse). In cirrhosis, type I and III collagen, as well as other components of extracellular matrix, deposit in all portions of lobules, thus causing endothelial cells of the sinusoids to lose their fenestrations. Furthermore, bypasses generate between the porta vein and the liver vein, as well as between the liver artery and the portal vein. All these processes finally transform the sinusoids of fenestrated endothelial channels, where interexchange of solutes between plasma and hepatocytes is free, into vascular channels of a greater pressure and slow flow, in which such solute interexchange does not take place. The impairment is especially marked in the movement of proteins between hepatocytes and plasma.

The greatest part of collagen excess present in cirrhosis seems to come from perisinusoidal Ito cells or stellate cells that store fat and are located in the space of Disse. Although, in normal conditions, their main function is to store vitamin A and lipids, during

cirrhosis development they activate and lose their retinol ester deposits and transform into myofibroblastic cells. The stimuli for collagen synthesis and deposit can come from several sources:

- chronic inflammation with synthesis of inflammatory cytokines, TNF, IL-1.
- cytosine production by stimulated endogenous cells (Kupffer cells, endothelial cells, hepatocytes, and epithelial cells in biliary ducts).
- alteration of extracellular matrix.
- direct stimulation of stellate cells by toxins.

TYPICAL NAFLD AND NASH LIVER LESIONS

Histopathologically, non-alcoholic fatty liver disease (NAFLD) is classified into two categories: only hepatocellular steatosis, and nonalcoholic steatohepatitis (NASH), where necroinflammatory damage appears associated with steatosis.

Simple steatosis generally has a benign clinical course, but one third of NAFLD cases progress and advance to NASH, liver cirrhosis and hepatocellular carcinoma (HCC).

The histopathological characteristics of NASH have been established since 2002. The necessary components for the diagnosis of NASH are: steatosis (accentuated in zone 3), lobular inflammation (mixed, mild) and hepatocellular ballooning (most apparent near steatotic liver cells, typically in zone 3). Fibrosis is not necessary for the diagnosis of NASH, although it is usually present.

Most hepatopathologists diagnose NASH according to these criteria, although a complete consensus has not been reached, as we will later explain.

Below are explained the histopathological features of adult NASH. (Figure 1.)

Figure 1. Histopathological lesions in NASH liver. A. hematoxiline-eosin, 100x. B. Portal inflammatory infiltrate. 200x. C and D. Hepatocellular steatosis. 400x.

1. Hepatocellular Steatosis

More than 5% of hepatocytes with steatosis is the hallmark of NAFLD.

It is usually macrovesicular, as a single large fat droplet nearly fills or occupies the cytoplasm of hepatocytes, pushing the nucleus to the periphery.

In few cases it can be observed where the cytoplasm of hepatocytes is filled with tiny lipid droplets and the nucleus is located centrally in the cell.

It usually begins in zone 3, and as the disease progresses, liver affection extends and becomes severe steatosis. This latter may end up being panacinar steatosis. As the severity of steatosis increases, other accompanying lesions appear as lobular inflammation and zone 3 fibrosis.

In cases of panacinar steatosis, it appears associated with ballooning, Mallory-Denk bodies (MDBs) and advanced fibrosis

2. Hepatocellular Ballooning

Ballooning hepatocellular injury is the other key diagnostic feature of steatohepatitis.

This lesion reflects hepatocellular injury. It is characterized as having swollen or “balloon-shaped” hepatocytes that lose the sharp angles and exhibit a clear and non-vacuolar cytoplasm.

These hepatocytes may or may not be larger than non-pathological hepatocytes, fat droplets and/or Mallory-Denk Bodies (MDBs) may be observed in their cytoplasm.

Studies using electron microscopy and immunostaining have evaluated the nature of ballooned hepatocytes. It results from alteration of cytokeratins 8 and 18, the cytoskeleton intermediate filament; they are disrupted and dispersed to the periphery.

In slides stained with hematoxylin and eosin, the recognition of ballooned hepatocytes may be difficult; the loss of cytokeratin 8/18 immunostaining can serve as an objective marker of ballooned hepatocytes.

3. Inflammatory Infiltrate

This can be lobular and portal inflammation.

The lobular inflammation in NASH is usually mild and, when abundant, suggests another or associated causes such as alcohol or drug toxicity.

It consists of a mixed inflammatory cell infiltrate: lymphocytes, neutrophils, eosinophils and Kupffer cells (KC).

It is possible to find an infiltrate predominantly lymphocytic.

Aggregates of neutrophils are rare in NASH and only become prominent around very damaged hepatocytes, and then we can observe ballooned hepatocytes with MDB in the cytoplasm surrounded by neutrophils. This lesion is referred to as “satellitosis”. Satellitosis can be occasionally seen in NASH, but is more common in alcoholic hepatitis.

KCs aggregates near sinusoidal capillaries are often found in NASH. They form sparse lobular microgranulomas.

Likewise, lipogranulomas, fat droplets mixed with inflammatory cells and collagen also appear.

Portal inflammation in NAFLD/NASH is usually absent or mild, and consists mainly of lymphocytes. Greater than mild and chronic portal inflammation is associated with the amount and location of steatosis, ballooning and advanced fibrosis. Therefore, it could be considered a marker of advanced disease. Finally, when portal inflammation is disproportionately severe, the possibility of concurrence with other liver diseases as hepatitis C or autoimmune hepatitis should be considered.

4. Fibrosis

Fibrosis is a major feature since the stage of fibrosis influences overall and liver related mortality, regardless of the presence or severity of other histological features.

Fibrosis in NASH is observed and associated with an active necroinflammatory reaction. It has a characteristic pattern: perisinusoidal or pericellular and typically begins in zone 3 as a delicate perisinusoidal deposition.

Usually periportal fibrosis develops, with or without zone 3 pericellular fibrosis. In cases of evolution and worsening of the diseases, bridging fibrosis and end-stage cirrhosis appears. In very advanced cases of fibrosis or cirrhosis, steatosis and necroinflammatory reactions disappear. This state is known as burn-out NASH or cryptogenic cirrhosis.

Particularly in adult NAFLD patients' post-obese intervention, it is possible to see very fine non-zonal sinusoidal fibrosis or any stage of fibrosis without any features of NASH.

NASH-related cirrhosis is most commonly macronodular or mixed.

5. Glycogenated Nuclei

Glycogenated nuclei are vacuolated nuclei observed usually in periportal hepatocytes, and commonly occur in NASH. The presence of glycogenated nuclei is useful for discriminating between NASH and alcoholic steatohepatitis (ASH), as they are rarely observed in ASH.

6. Apoptotic Hepatocytes (Acidophil Bodies)

Often we can observe apoptotic hepatocytes in NASH. These are found in sinusoids as eosinophilic rounded bodies, with hyperchromatic nuclear fragments.

7. Mallory-Denk Bodies (MDBs)

They are eosinophilic irregular-shaped aggregates found in the cytoplasm of hepatocytes.

These structures are usually observed in ballooned hepatocytes in zone 3, and mainly consist of cytokeratins 8 and 18, ubiquitin, and p62.

The presence of MDBs is not definitively required, but is helpful for the diagnosis of NASH. MDBs are not specific to NASH; they are also observed in other liver diseases including chronic cholestasis, HCC and alcoholic hepatitis, where MDBs are also observed in non-ballooned hepatocytes.

8. Iron Deposition

Iron accumulation in NAFLD/NASH is usually mild, and can occur within hepatocytes, the sinusoidal lining cells of the reticuloendothelial system, or both.

The signification of iron deposition in NASH remains unclear. Alenti et al., in 2010, reported that iron accumulation was predominant in hepatocytes and was associated with advanced fibrosis in NASH. However, Nelson et al., in 2011, indicated that NASH patients with iron accumulation in the reticuloendothelial system were more likely to have advanced fibrosis compared to patients with iron accumulation in hepatocytes.

9. Megamitochondria

They are crystal-shaped eosinophilic structures in the cytoplasm of hepatocytes. They may be the result of injury from lipid peroxidation, or could represent an adaptive change.

They are observed most commonly in hepatocytes with microvesicular steatosis. Megamitochondria in NASH are distributed equally in all zones, and are abundant similarly in low- and high-stage groups.

10. Ductular Reaction

This refers to ductular proliferation at the portal tract interface. It arises from progenitor cells in the periportal area, and is accompanied by neutrophils and stromal changes. In NASH, the extent of ductular reaction is associated with fibrosis.

11. Steatohepatic Hepatocellular Carcinoma (SH-HCC)

NASH can progress to liver cirrhosis and HCC.

However, the pathological features of HCC derived from NASH have not been elucidated.

In 2009, the 5-year incidence of HCC for cirrhotic NASH was reported to be 11.3%.

In 2010, Salomao et al., described a distinctive histological variant of HCC that they termed SH-HCC. SH-HCC shows features that resemble non-neoplastic steatohepatitis, including large droplet steatosis, ballooning of malignant hepatocytes, MDBs, inflammation, and pericellular fibrosis.

In a 2012 study, the same group reported that the prevalence of SH-HCC in all HCC cases was 13.5%. Almost all cases of SH-HCC occurred in patients with underlying

steatohepatitis. It was diagnosed in 35.7% of HCC patients with either NASH or alcoholic liver disease, compared with only 1.3% of HCC patients with other chronic liver diseases.

Subsequently, Jain et al. in 2012, reported that SH-HCC was much more common in cirrhotic NASH patients compared with those with alcoholic cirrhosis.

ASSESSMENT SCALES

There are different histopathological scoring systems. All share the assessment of four histological lesions: extent of steatosis, grade of inflammation, hepatocyte ballooning, and staging of fibrosis. All have both pros and cons which will be discussed here.

The methods currently used to semi-quantitatively evaluate the histological lesions of NAFLD and to cover the spectrum of the disease are:

- the NAFLD Activity Score (NAS) and Fibrosis Score by the NASH Clinical Research Network (NASH-CRN).
- the 'Fatty Liver Inhibition of Progression (FLIP)' Algorithm and Steatosis, Activity, and Fibrosis (SAF) Score.

The first scale proposed by Brunt et al. in 1999 was purely histological.

In 1999, there were no systems for grading necroinflammatory activity or fibrosis as did exist for various other forms of chronic liver disease. Brunt EM et al., wanted to develop such a grading system. After the revision of liver biopsies from patients with nonalcoholic steatohepatitis from Saint Louis University Health Sciences Center, they concluded that histological lesions considered to be significant were: steatosis, ballooning, and intra-acinar and portal inflammation. They developed a staging score where they classified the necroinflammatory grades of NASH as grade 1 (mild), grade 2 (moderate), and grade 3 (severe) based on the degree of hepatocellular steatosis, ballooning and inflammation (intralobular and portal). (Table 1). The range is from 0 to 8.

Steatosis grade ranges 0 to 3, where normal liver (grade 0) contains fat in < 5% of hepatocytes, and grade 1, grade 2, and grade 3 steatosis refer to at least 5%, 33%, or 66% of steatotic hepatocytes, respectively.

Lobular inflammation is graded 0 to 3 based on the number of inflammatory foci in a given area.

Grading of ballooning ranges 0 to 2 and is mainly based on the number of ballooned hepatocytes.

For staging and quantifying liver fibrosis based on the location and extent of fibrosis, the scoring system is: stage 1, zone 3 perisinusoidal fibrosis; stage 2, portal fibrosis with the abovementioned stage 1; stage 3, bridging fibrosis in addition to stage 2; and stage 4, cirrhosis.

In 2005, The NASH Clinical Research Network (NASH CRN) designed and validated the histological NAFLD Activity Score (NAS) scoring system that addresses the full spectrum of NAFLD/NASH lesions. (Table 2).

Table 1. NAFLD/NASH Scale proposed by Brunt et al. in 1999

GRADING	Grade 1 (MILD)	Steatosis up to 66%
		Ballooning: occasional in zone 3
		Intralobular inflammation: scattered polymorphs ± lymphocytes
		Portal inflammation: no or mild
	Grade 2 (MODERATE)	Steatosis: any degree
		Ballooning: obvious, predominantly zone 3
		Intralobular inflammation: polymorphs and chronic inflammation noted
		Portal inflammation: mild to moderate
	Grade 3 (SEVERE)	Steatosis: panacinar
		Ballooning: ballooning and disarray obvious, predominantly in zone 3
		Intralobular inflammation: scattered polymorphs ± mild chronic inflammation
		Portal inflammation: mild or moderate.
STAGING	Stage 1	Zone 3 perisinusoidal/pericellular fibrosis, focal or extensive
	Stage 2	Zone 3 perisinusoidal/pericellular fibrosis + focal or extensive periportal fibrosis
	Stage 3	Zone 3 perisinusoidal/pericellular fibrosis + portal fibrosis + bridging fibrosis
	Stage 4	Cirrhosis

It is based on the notion in liver disease that the necroinflammatory lesions and the stage of fibrosis should be separately evaluated because the former are potentially more reversible than the latter.

Table 2. NAFLD/NASH Scale proposed in 2005 by The NASH Clinical Research Network (NASH CRN)

NAFLD ACTIVITY SCORE(NAS) and FIBROSIS SCORE By the CLINICAL RESEARCH NETWORK (NASH-CNR)			POINTS
	Steatosis(S)	< 5%	0
		5 - 33%	1
		34 - 66%	2
		> 66%	3
	Lobular Inflammation(LI)	0	0
		< 2/20x	1
		2 - 4/20x	2
		> 4/20x	3
	Ballooning (B)	None	0
		Few	1
		Many	2
	Fibrosis Stage(F)	None	0
		Zone 3 perisinusoidal, delicate	1a
		Zone 3 perisinusoidal, dense	1b
		Portal only	1c
		1 ^a or 1b + portal	2
		bridging	3
		Cirrhosis	4
SCORES	NAS: S + LI + B = 0 - 8		

Based on Brunt, they classified the necroinflammatory grades of NASH as grade 1 (mild), grade 2 (moderate), and grade 3 (severe) according to the degree of hepatocellular steatosis, ballooning and inflammation (intralobular and portal).

NASH CRN subclassified Bunt stage 1 into 3 categories: stage 1A, mild perisinusoidal fibrosis in zone 3; stage 1B, moderate perisinusoidal fibrosis in zone 3; and stage 1C, only portal/periportal fibrosis. Stage 1C fibrosis is observed occasionally in children or severely obese patients.

Currently, the NAS is one of the most widely used histological classifications for NAFLD/NASH and its use is recommended for defining and quantifying disease activity in observational and interventional trials of NAFLD/NASH.

But, accumulating evidence indicates that the NAS is poorly correlated with metabolic risk factors and is unable to predict both the risk of fibrosis progression [and (liver-related and overall) mortality in NAFLD.

In 2012, Bedossa et al., wanted to build an algorithm along with a scoring system for histopathologic classification of liver lesions that covered the entire spectrum of lesions in morbidly obese patients.

They suggest that the SAF score evaluates the grade of steatosis (S), the grade of activity (A), and the stage of fibrosis (F). The A grade (A0 to A4) is computed by adding grades of ballooning to lobular inflammation.

They built an algorithm for the histopathological lesions segregating lesions into normal liver, NAFLD, or nonalcoholic steatohepatitis (NASH) based on semiquantitative evaluation of steatosis, hepatocellular ballooning, and lobular inflammation. For each case, the SAF score was created including the semiquantitative scoring of steatosis (S), activity (A), and fibrosis (F).

Compared to the NAS score, the SAF scores the grading of hepatocellular ballooning based chiefly on both size and shape of ballooned hepatocytes.

At variance with the NAS, the SAF score does not include steatosis in the activity score. The philosophy behind this is that, compared to hepatocellular ballooning and lobular inflammation, steatosis *per se* is an arguable prognostic marker of disease progression. Moreover, the fibrosis stage, although an acknowledged outcome modifier in chronic liver disease owing to various etiologies, is not part of NAS.

The SAF score allows for the definition of categories of NAFLD severity (mild disease when $A < 2$ and $F < 2$ vs. significant disease when $A \geq 2$ and/or $F \geq 2$), defined by hepatocellular ballooning, lobular inflammation, and fibrosis, that is, those parameters of recognized prognostic significance in NAFLD.

In 2014, the European FLIP (Fatty Liver Inhibition of Progression Consortium) designed the FLIP algorithm based on the SAF score to decrease interobserver variations among pathologists and to be implemented in pathology practice. The aim of this study was to determine whether the use of the SAF score and FLIP algorithm can decrease interobserver variations among pathologists. The FLIP algorithm based on the SAF score should decrease interobserver variations among pathologists and is likely to be implemented in pathology practice.

The FLIP algorithm (Table 3) is based on semi-quantitation of the three elementary liver histological features. Steatosis is graded 0 to 3, ballooning 0 to 2, and lobular inflammation 0 to 2.

Table 3. NAFLD/NASH Scale proposed by European FLIP (Fatty Liver Inhibition of Progression Consortium) in 2014

SAF/FLIP ALGORITHM			POINTS
	Steatosis(S)	< 5%	0
		5 - 33%	1
		34 - 66%	2
		> 66%	3
	Lobular Inflammation(LI)	0	0
		< 2/20x	1
		2 - 4/20x	2
		-	-
	Ballooning (B)	None	0
		Clusters, reticulated cytoplasm	1
		Enlarged hepatocytes	2
	Fibrosis Stage(F)	None	0
		Zone 3 perisinusoidal, (all), or portal only	1
		Zona 3 + periportal	2
		-	-
		-	-
		bridging	3
		Cirrhosis	4
SCORES	SAF: S + ACTIVITY(A: LI + B) + FIBROSIS = S0 - 3 A0 - 4 F0 - 4		

The FLIP algorithm aims at enabling a binary classification: NASH as opposed to “steatosis without NASH”. NASH is diagnosed based on the combination of all three elementary histological features provided that each of these three features has a grade ≥ 1 .

DIFFERENTIAL DIAGNOSIS BETWEEN NASH AND OTHER DISEASES AFFECTING THE LIVER

After a complete and detailed medical history, obviously taking into account clinical information regarding alcohol intake, a differential diagnosis with the following diseases should be made:

- alcoholic liver disease (ASH).
- drug-induced liver injury.
- Wilson’s disease.
- α 1-antitrypsin deficiency.
- viral hepatitis.

From a histological point of view, the differential diagnosis between NASH and ASH is the most frequent. The main differences with ASH are:

1. Features that are more common in NASH than ASH include severe steatosis, glycogenated nuclei, and lipogranulomas. Fibrosis in NASH shows a lattice pattern.
2. Histological features more common in ASH than NASH include:

- Canalicular cholestasis.
- MDBs in ASH are numerous and well formed.
- A prominent ductular reaction.
- Acute inflammation and fibrosis in the portal tract.
- Fibrosis in alcoholic liver disease shows a solid pattern on reticulin-stained slides.
- Necroinflammatory activity in ASH is more severe than in NASH.
- Sclerosing hyaline necrosis and veno-occlusive lesions are observed occasionally in alcoholic liver disease, but these lesions have not been reported in NAFLD.

Chapter 307

LIVER BIOPSY AS THE “GOLD STANDARD” IN NASH DIAGNOSIS

***Soledad García-Gómez-Heras*, MD, PhD,
Julio Paredes-González and Raquel Franco-Rodríguez***

Human Histology and Pathology, Health Science Department,
Rey Juan Carlos University, Madrid, Spain

ABSTRACT

Liver biopsy is the “gold standard” for the diagnosis and evaluation of NAFLD/NASH disease. It is an invasive procedure but we can confirm, characterize the severity of parenchymal changes, and distinguish between NAFLD, steatohepatitis and NASH, associated with the progression of liver injury. Also, it provides a semi-quantitative evaluation of the severity of injuries (Assessment Scales), extremely useful in clinical trials.

The histological and anatomopathological study is a set of procedures fully used both for diagnoses and for investigation. Such procedures require meticulous care in their elaboration due to the sensitivity of these techniques. The different steps in the processing of the tissue are explained in this chapter.

Keywords: liver biopsy, diagnosis, histopathology, NASH, NAFLD, gold-standard

INTRODUCTION

Liver biopsy is the “gold standard” for the diagnosis and evaluation of NAFLD/NASH disease. The histopathological evaluation of liver biopsy samples remains central in a patient with clinical signs of NAFLD to exclude other causes of chronic liver disease, to confirm or to exclude the diagnosis of NAFLD/NASH, to evaluate the severity if it is confirmed and to demonstrate if patients have cirrhosis.

* Corresponding Author’s Email: soledad.garcia@urjc.es.

Advantages of Liver Biopsy

Liver biopsy plays a unique role compared to non-invasive assessments; thanks to the biopsy we can confirm and characterize the severity of parenchymal changes, distinguish between NAFL, processes that are considered to be slowly progressive, and steatohepatitis, NASH, associated with the progression of liver injury. Also, it provides a semi-quantitative evaluation of the severity of injuries (Assessment Scales, see below), extremely useful in clinical trials.

None of the non-invasive techniques tests can determine if liver injury and fibrosis is really due to NAFLD or to another coexistent liver disorder. On the one hand, nor ultrasound nor computerized tomography (CT) can determine if patients actually have NASH.

On the other hand, elastography and magnetic resonance imaging (MRI) attempt to diagnose NASH base on the assessment of fibrosis and presume that patients with suspected NAFLD and fibrosis have NASH.

Disadvantages of Liver Biopsy

It is an invasive procedure, which requires hospitalization in nearly 3% of cases and is complicated by a 0.3% mortality.

Liver biopsy does have risk of clinical complications, small but real, including:

- pneumothorax.
- pain.
- significant bleeding, 0.3% of persons with a normal platelet count and normal levels of clotting factors.

Additionally, the histopathological NAFLD liver lesions are not uniformly distributed; the liver is not affected homogenously and as the size of biopsy sample represents a small fraction of the entire organ, the significance of the sample is a subject that should be taken into account.

Because all the above, liver biopsy cannot be considered as a screening procedure in high-risk patient populations; liver biopsy is also unsuitable in long-term monitoring of patients with NAFLD and assessing their response to therapy. Thus, it should definitely be restricted only to those patients who have a high probability of significant liver fibrosis.

Gunn et al. proposed that a liver biopsy should be performed in the following cases:

- All features of metabolic syndrome and obesity.
- T2DM and elevated liver transaminases.
- Normal BMI with elevated liver transaminases
- Elastography greater than 6 kPa.
- Elevated value with a fibrosis scoring system.
- Reliable elastography value cannot be obtained because of obesity.
- Patients are not motivated to lose weight.

And a deferred Liver biopsy when:

- Two or fewer features of metabolic syndrome.
- Normal liver transaminases and absence of T2DM.
- Elastography less than 6 kPa.
- Low value with a fibrosis scoring system.
- Patients are motivated to lose weight.

PROCESSING OF LIVER SAMPLES OBTAINED BY BIOPSY

The histological and anatomopathological study allows us to observe tissues and their different structures, the cells that make it up, and even their ultra-structure through a set of techniques called histological techniques. This set of procedures is fully used both for diagnoses and for investigation. Such procedures require meticulous care in their elaboration due to the sensitivity of these techniques. Therefore, one needs to be aware that an incorrect procedure in any of these steps will produce an altered image that could lead to incorrect results.

Biopsy Types

Samples for the histological study come from biopsies. The biopsy is a surgical procedure from which a small cell tissue sample is obtained from a lesion, tissue or organ for subsequent processing and study under a microscope. Depending on the amount of extracted material and the method used, biopsies can be classified in several types:

1. Incisional Biopsy

Incisional biopsy is that in which only a piece of tissue, mass, or tumor is surgically obtained. Two additional types can be found inside this category:

- *percutaneous biopsy*. The sample is obtained by introducing a needle into the tissue or lesion. The result is a tissue cylinder whose thickness depends on the needle's gauge. Based on the gauge, they are classified in FNAB (fine-needle aspiration biopsy) or CNB (core-needle biopsy).
- *endoscopic biopsy*. The sample is obtained using an endoscope, which is a thin flexible tube that has a light source and a camera at one end. This camera relays high resolution images of the studied site to a television screen.

2. Excisional Biopsy

Excisional biopsy is that in which a full organ, tumor or lesion is surgically obtained.

In this chapter, we will focus on liver biopsy. The study target and source for the samples in this biopsy is the liver. Sampling takes place through percutaneous biopsy, transvenous and/or laparoscopic biopsy.

Percutaneous liver biopsy is the most used. It involves the introduction of a thin needle through the abdomen to reach the liver in order to draw a sample. The sampling is assisted by imaging methods, such as echography or computed tomography. Two types of needles are used for the liver puncture, thus generating two different hepatic cylinders. In one of them, the cylinder is obtained by means of the cut, as with Trucut or Vin Vilverman needles; in the other by means of suction, as with Menghini, Klatskin or Jamshidi needles. In recent years, a new type of automatic needle for biopsies has been developed. This is Trucut-type needles for trimming, which do not need manual handling.

Transvenous liver biopsy takes place by introducing, through the jugular vein, a specially designed hollow tube that allows for the introduction, inside of it, of a biopsy needle, as well as for the extraction of tissue samples when the liver is reached.

Laparoscopic liver biopsy is guided by a laparoscope, which is a flexible tube that has a light and a camera. It is introduced in the abdominal cavity through small incisions. Air is then inserted into the cavity leaving an observation and working area, in order to monitor the liver state on the surface, and to take samples in areas of interest.

Processing of the Tissue (Figure 1)

Figure 1. The steps in the processing of liver samples obtained through biopsy. A. Fixation. B. Paraffin embedding. C. and D. Block preparation. E. Obtention of tissue cuts with a minot-type microtome. F. Staining the samples.

1. Fixation

Whatever the means of obtaining the tissue sample, the first step after obtaining the sample is the sample fixation process. This is of vital importance, because it will be a determinant for good development of the other procedures. With this process, we intend to preserve the tissue for study in a state as close as possible to what it was when it was in vivo. To do this, we need to prevent cell autolysis and to stop enzymatic processes. We also have to avoid the action of bacteria, which would start putrefaction processes. And, at the same time, we also want to provide the sample with the hardness necessary for handling it easily, and for its posterior sectioning process.

In order to have the sample fixed correctly and efficiently, the following premises should be taken into account:

- The tissue must come into contact with the fixation agent as soon as possible. The best way to do this is to make a perfusion. To do so, liquid fixative is introduced into the circulating system so that it reaches the tissue. Obviously, such process is not possible in a hospital biopsy, and is normally more used in test animals.
- The volume of liquid fixative should be ten to twenty times greater than the volume of the sample, in order to let it work more efficiently. The fixative is recommended to be at a temperature of 4°C-5°C. The sample must be free of blood, mucus, or any other product that could hinder the liquid fixative's penetration into the tissue. Therefore, it is recommended to rinse the sample with physiological or buffered saline solution (in order to prevent an osmotic imbalance from damaging the specimen). Likewise, the liquid fixative used should have an osmotic balance with the sample. To be sure, saline solutions can be used as a solvent for the fixation agent.
- Sample size. The type of tissue should also be born in mind. If we are going to work with a compact or lax tissue, the liquid fixation agent will be able to penetrate with more or less ease. If the tissue presents membranes hampering the fixative's introduction, and of course, the thickness of the sample: it is always recommended to have a thin sample with edges being as flat as possible.
- The fixative should not cause any alterations in the tissue, such as retractions or swelling, or any change that could affect its morphology. Any variations introduced in the tissue, should be in order to make the posterior handling of the piece easier, or to improve its tinctorial strength.
- The specimen's fixation time must be optimal. It is not recommended to leave the tissue in the fixation agent too long or, obviously, too little time. The optimal time depends on the type of fixative or the fixative mixture used. Each one has an ideal fixation time, which should be followed.

There are several ways to classify fixatives. One of the main ways is depending on whether they act physically or chemically on the tissue. *Fixation through physical processes* takes place by freezing the tissue. This method presents advantages and disadvantages. The main advantage is speed and wide conservation of antigens, enzymes, and proteins, which makes it a very useful fixation for intraoperative biopsies, and for histochemical and immunohistochemical techniques. Some of its weaknesses are the short durability of the

samples, the need for expensive frozen storage systems, the huge risk of breaking tissue structures during the freezing process despite using buffered solutions to prevent the formation of crystals in the cells, etc. The most widely used substances for freezing are liquid nitrogen and isopentane at -50°C , which is the most commonly used for cryodesiccation and cryosubstitution.

Tissue *fixation through chemical processes* takes place through chemical substances that are normally used in an aqueous solution. They act on the tissue by stabilizing it and stopping its processes, while they also act as a bactericide to preserve it. They can be classified as simple or compound fixatives, based on the amount of substances that comprise them: just one or several.

They can also be classified according to how they act on the tissue.

Some fixatives act by dehydrating tissue. They generate protein denaturing, leading to a quick outflow of water from the tissue structures. Some examples are methanol, chloroform, ethanol and acetone.

There are also fixatives whose action takes place through *salt formation*. These normally have a great capacity to penetrate the tissue, and these fixatives spread throughout tissues at a rapid pace. But, at the same time, they present the disadvantage that the formation of those salts creates a crust on the sample, thus minimizing penetration. Therefore, they are normally adequate to be used in fixation mixtures, but are rarely used individually. Examples of these fixatives are mercury chloride or “corrosive sublimate”, which is very often used for hematopoietic pathologies, potassium dichromate, which is very good for preparing tissues for silver impregnation techniques, or the picric acid, which is useful as it does not dissolve fat or glycogen, and has a slight decalcification action.

Others take action through *protein reticularization*. They generate protein denaturation, in which hydrogen bridges break, and a reticular polypeptide net is generated. Formaldehyde and formol, with all their variations, glutaraldehyde or osmium tetroxide, which are used in electronic microscopy techniques, are some of the fixatives in this group.

Since *formaldehyde and formol* are part of the most used fixatives, their advantages and disadvantages will be discussed a bit deeper. Formol is used so frequently because of its versatility for fixing all tissue structures. Its tissue penetration rate is not as rapid as other fixatives acting through dehydration, but it still is well above fixatives acting by forming salts. It performs very well as a bactericide and causes almost no tissue alteration phenomena, such as retraction or an excessive hardening. It is effective for the fixation of lipid structures, and normally leaves no deposits in the tissue nor does it interfere with posterior staining. It is very affordable, and can be used both as a single fixation agent, and in fixative mixtures. Its main disadvantages include irritating vapors and its current classification by the European Parliament as a carcinogen category 1B and mutagen category 2. Therefore, it must always be used with all protection measures available. It is also unstable when exposed to sunlight and the atmosphere. If the pH of the formol dissolution decreases below 6, crystals called formolic pigments may start depositing in the tissues, thus altering the posterior staining image. In order to solve these stability problems, the pH, and to improve any issues that could arise due to osmotic differences with the sample, formol 4% is normally used in a buffer solution such as a phosphate, which we call buffered formol.

Finally, there are *fixatives that act through changes in the colloidal state*. They decrease the pH of colloidal solutions where there are proteins and make them precipitate. Among them, we find acetic acid, which preserves nucleoproteins and nucleic acids well, and chromic

acid, which is an excellent structural fixative, and acts as mordant of the tissue in stainings where basic coloring will be used.

Regarding *fixative mixtures*, they can be divided into formol-containing or formol-free mixtures. Below, some examples are listed. Among the fixative mixtures with formol, the following can be found:

- *Bouin's solution*: its fixation time goes from 4 to 24 hours, depending on the sample thickness. It requires posterior washes in ethanol at 80% until picric acid remnants are removed. It requires special attention to prevent the piece from hardening too much due to the successive washes in ethanol. It is recommended to include the sample immediately after that. This fixation is efficient in embryonic or testicular samples, and acts as mordant in techniques such as Masson's trichrome staining. However, it is discouraged in kidney samples, due to the alterations generated in the resulting image.
- *Ciaccio's fixative*: its fixation time is 48 hours, and after that, a wash under running water for 24 hours is required. Using this fixative is recommended for lipid tissues or with high fat content.
- *Susa-Heidenhain mixture*: its fixation time goes from 1 to 12 hours. After that time, samples require washes in ethanol 80%. Afterwards, they can be preserved in ethanol 70% for a while. This mixture presents a slight decalcification power.

Among the fixative mixtures that contain no formol, are the following:

- *Carnoy's solution*: This mixture has a maximum fixture time of 2 hours, due to its great capacity for penetrating tissues. Afterwards, samples must be washed with absolute ethanol. Apart from the fixation process, this mixture also acts as sample dehydrating, leaving this step ready for posterior inclusion. It is a much recommended fixation to preserve nucleic acids, Nissl lumps, fibrillary proteins, myofibrilles, and glycogen.
- *Zenker's fixative*: This mixture requires a solution made at the time of use. Its maximum fixation time goes from 2 to 48 hours. Samples fixed in Zenker, once cut and deparaffinized, need to undergo a process called dezenkering. This involves treating the sample with an iodized solution, and then with a sodium thiosulfate solution to remove residues that mercury salts leave on the tissue. This fixation is much used for bone marrow and other hematopoietic tissues, as well as for lymphoid tissue, due to the good preservation of nuclei. It also acts as a mordant in some stainings, such as the phosphotungstic acid-hematoxylin stain.

We would also like to mention the fixation patterns that require histological techniques such as *electron microscopy*. Samples for transmission or scanning electron microscopy need a fixation according to the special needs required for the observation of samples at such magnifications and the particular workings of these microscopes. In these cases, a double or triple fixation is used. The first agent normally is a fixative belonging to the aldehyde family (glutaraldehyde is the most frequently used), although formaldehyde or even other types of fixatives such as potassium permanganate or uranyl acetate can also be used. Based on the

ultra-structures that we want to observe, some fixatives will be more adequate than others. It is of vital importance that the fixative be in a buffer solution favoring a stable pH, with no changes in the sample's osmolarity, and that it have an appropriate ionic constitution so as to prevent the cell components from being extracted or precipitate during the fixation process. One of the most used is 2% glutaraldehyde in phosphate or in cacodylate buffer solution. After this fixation, samples are fixed again in an osmium tetroxide solution at 1% buffered solution. Before this second fixation, and given the slow penetration rate of both fixatives, the samples need to be cut or "carved" creating 1 cubic millimeter in order to promote their correct fixation and to facilitate cutting and handling of the samples, in addition to the posterior observation under the microscope. After the second fixation, the third one should be with uranyl acetate as the fixative agent. The third fixation can be skipped depending on the specific needs of the sample.

2. Embedding

After the fixation of the tissue, and for its posterior observation and study in the microscope, the embedding process must start. The objective of embedding is to provide the sample with a determined consistency or hardness so as to allow for later obtaining sections or cuts of the tissue. This will also prevent fragmentation and will preserve the structure and characteristics of cells with very little interference. As far as possible, such cuts, should be fine, regular and homogeneous.

The consistency and hardness needed for the tissue is obtained by infiltrating liquid substances into the tissue. They will subsequently solidify due to refrigeration or polymerization, and the desired hardness will be obtained. Based on the sample type, and bearing in mind the technique selected for the posterior study, we can choose from among the embedding media types. According to the characteristics of embedding media, they can be classified into:

- *Hydrophilic* embedding media: such as gelatin, polyethylene glycol, and OCT.
- *Hydrophobic* embedding media: such as paraffin, celodine, and different types of resins (such as acrylic, polyester, or epoxy resins).

Tissue Embedding in Hydrophilic Embedding Media

Bearing in mind that tissues are mainly composed of water, and that hydrophilic embedding media are soluble in water, this type of embedding allows us to work directly with the hydrated tissue. Within this embedding type, we find, among others:

Gelatin

If the tissue has previously been fixed, before starting gelatin embedding, such fixture has to be removed from the tissue through washes in running water. Since gelatin is water soluble, there is no need to dehydrate or rinse the tissue. Another advantage of gelatin is that its melting point is low. Therefore, tissue samples are spared the downsides of working with high temperatures (>40°C) during the process. Embedding takes place by means of successive baths in gelatin with different increasing concentrations at 37°C.

OCT (Optimal Cutting Temperature Compound)

The OCT is composed of polyvinyl alcohol, polyethylene glycol, and reserved composition excipients (Ames type) acting as cryoprotectants.

This type of embedding is currently the most widely used for obtaining frozen cuts, because it favors cutting in cryostats at very low temperatures (-20°C) and, therefore, allows us to work with samples with no need for previous fixation.

Tissue Embedding in Hydrophobic Embedding Media

These embedding media, since they are not water miscible, force us to perform a series of previous steps to the embedding media in order to remove all the water that the tissue contains. If the sample is not correctly embedded in the embedding medium, it will spoil, and performing regular and homogeneous cuts will be very difficult. Among hydrophobic embedding media, paraffin is currently the most often used. We also find celoidine, but less frequently. There are other embedding hydrophobic media, such as different types of resins (acrylic, polyester, epoxy), that are chosen based on the type of technique subsequently used and the type of microscopy used for the visualization. Since paraffin is the most common embedding medium, we will focus on it, and will use paraffin to explain the different steps needed and in common, with certain differences for all embeddings with hydrophobic embedding media.

Paraffin Embedding

Paraffin is formed by mixtures of saturated hydrocarbons. It is solid at room temperature, and depending on its type of hydrocarbon mixture, has a melting point ranging from 40°C to 70°C. The most used paraffins normally have a melting point around 60°C.

Paraffin is not water miscible. And taking into account that most fixatives, and tissues themselves, contain water, we have to take a series of steps to replace that water with an organic solvent to allow the liquid paraffin to correctly embed the tissue. We divide those steps into:

1. *Dehydration.* Dehydration is the process by which water is completely removed from the sample to be embedded. It takes place by means of chemical agents or dehydration reactants, or through physicochemical procedures (cryodesiccation and cryosubstitution). The dehydration process takes place through repeated baths in increasing alcohol content solutions (50°, 70°, 80°, 96°, 100° (absolute alcohol)). It is performed gradually so as to prevent the tissue from retracting. According to the type of tissue and sample size, the optimal time and number of baths in different concentrations is calculated to avoid a too long exposition that could cause an excessive tissue hardening. The main dehydration agents are: ethyl alcohol (the most used), methyl alcohol, acetone, butyl alcohol, dioxane, isopropyl alcohol, etc. The main characteristics of a good dehydration agent are: it must not alter tissue structures and must be miscible with the intermediate solvent or the clearing agent that will be subsequently used.
2. *Clearing or dealcoholisation.* This is the process through which the dehydration agent is substituted by a substance miscible with the embedding medium that will be used. The clearing process takes place by means of successive baths in the chosen clearing agent. The duration and amount of these baths depends on the characteristics

of the clearing liquid and the type and size of the tissue sample. The selection of the clearing agent or the intermediate solvent will be mainly based on its own characteristics, including: speed for the removal of the dehydration agent, lack of hardening or tissue retraction, appropriateness to the dehydration agent and the embedding medium, etc. The main clearing agents or intermediate solvents are: xylene, toluene, chloroform.

3. *Infiltration or Impregnation.* This is the process through which we fully infiltrate or fill the tissue sample with the chosen embedding medium. The objective of this process is to completely occupy with inclusion medium the space that was previously occupied with the water contained in the tissue. This way, we provide the homogeneity and hardness necessary for obtaining fine quality cuts of the study sample. The infiltration or impregnation process takes place through successive baths in liquid paraffin. These baths must be changed frequently, since they get saturated with clearing agent and this could generate changes in paraffin characteristics, thus hampering the posterior trimming. The length and number of baths in liquid paraffin will depend, as always, on the characteristics of the chosen paraffin (and the inclusion medium of use at that moment), as well as the type and size of the tissue sample.

Currently, there are automatic processors, which have different vases or recipients to perform the baths in the different liquids and thermal vases for paraffins with a mechanic transport system across them that is regulated by a time programmer. This enables performing the embedding process on a high number of samples and optimizes time, since the process can continue over night.

4. *Block Preparation.* This is the process through which we obtain a tissue block embedded in the embedding medium through slow cooling until reaching 10°C-15°C. In order to facilitate sample identification, the embedding process and the posterior block preparation, the sample is placed in a kind of capsule or cassette. These cassettes allow for maintaining the sample immersed in a liquid by means of the opening for infiltration they have on their entire surface.

Apart from cassettes, for block preparation, we need special molds. These molds are normally metallic (favors cooling) and of different sizes than can be adjusted to the sample size. These molds fit perfectly in the cassettes used for embedding. In summary, cassettes facilitate block preparation, their arrangement in the microtome for the obtaining of tissue sections or cuts, and their subsequent archiving.

In order to create the blocks, certain devices called “embedding stations” will be used. These stations have a liquid paraffin dispenser, a hot plate with light and a magnifier for sample orientation, and a cold plate for solidification of the block.

Tissue Embedding in Other Hydrophobic Embedding Media

Embedding media other than paraffin are normally chosen when the tissue characteristics so require such as when a tissue is too hard (undecalcified bones), when it contains structures that become affected by heat (enzyme study), when the tissue has several parts with different consistencies, or when the study requires very thick or very thin cuts. Among these other hydrophobic embedding media, plastic embedding stands out.

Plastic Embedding

This type of embedding uses acrylic resins (methylmethacrylate, glycol methacrylate, etc.) or epoxi type, and is based on the polymerization of an elemental substance of low molecular weight until transforming it into a solid, clear, and very hard compound. The following stand out:

- *Methylmethacrylate Embedding.* The elemental substance used here as an embedding medium is monomeric methylmethacrylate. This type of embedding is chosen for very hard tissue samples, such as undecalcified bones. One advantage of methacrylates is that their elasticity and hardness can be modified according to the amount of monomers that the final mixture contains. This allows for adapting to the tissue type to be embedded.
- *Embedding for Electron Microscopy.* To observe the cell's ultrastructure, it is indispensable to obtain very thin tissue cuts (nanometers), called ultrathin cuts, and to use a transmission electron microscope. In order to obtain ultrathin cuts, the tissue needs to be hardened. To that end, the most used media to embed tissue are the epoxi-type resins, or, less frequently, acrylic resins (methacrylate). In electron microscopy, the embedding process is very similar to paraffin embedding, since the same steps have to be followed, but with different substances: fixation (glutaraldehyde), post-fixation, dehydration (ethanol and acetone), intermediate solvents (epoxypropane or propylene oxide), embedding and polymerization in the embedding medium (60°C) (epoxy resins: araldite, Epon resin, Spurr's resin).

3. Obtention of Tissue Cuts

In order to observe the characteristics of the different tissues and their cell structures through various microscopes, very thin cuts need to be performed. Otherwise, problems with light diffusion and penetration appear in optical microscopes, and electron penetration in transmission electron microscopes. The ideal thickness of cuts for their correct observation ranges from a few nanometers to hundreds of microns. The thinner the tissue sample cut has to be, the harder the tissue needs to be. Its hardness will depend on the tissue characteristics, the fixation process, the embedding process, and the selection of the embedding medium. Another way of hardening the tissue is through freezing.

In order to obtain such cuts of tissue samples, some devices called microtomes are used. These devices allow for performing cuts of micrometric thickness, fine enough to be observed with microscopes. There are different types of microtomes, such as: oscillating or rocking microtome, Minot-type or rotary microtome, sliding microtome, freezing microtome, cryostat, cryomicrotome, and ultramicrotome. The selection of the microtome type will depend on the desired thickness of the cuts, the embedding medium where the tissue is immersed, and the tissue hardening process, which can be by freezing or embedding. Microtomes for tissues embedded in paraffin are the most commonly used for optical microscopy, and ultramicrotome for transmission electron microscopy. Cryostat is also frequently used for optical microscopy, since it allows for sectioning unembedded tissue, and even tissue without fixation, resulting in a time saving and an easier process.

4. Staining

Once our sample is cut, the next issue to address is the fact that human and animal tissues normally are colorless. Exceptions include certain parts where melanic pigments can be found in cells, colored erythrocytes, or some type of metallic deposits, or other materials coloring cell cytoplasm. Since sample structures are not apparent without staining, they need to undergo that process. To do so, we exploit the capacity of tissues to incorporate and fix colored substances in their interior.

These substances, which we call dyes, normally derive from benzene, which is an aromatic hydrocarbon with a characteristic ring in its molecular structure. These substances can have a natural origin, either plants or animals, or can derive from aniline, which is artificially obtained from tar or coal.

These dyes are classified according to their *staining affinity* for the various components of tissues. Thus, there are *alkaline dyes*, which are aniline molecules containing one or more positive charges in the molecule's colored portion. They have affinity for the acid structures of the tissue, such as nucleic acids, and nuclear structures, such as hematoxylin. *Acid dyes* are anilines that include negative charge in the molecule's colored portion. They show affinity for basic structures in cells and tissues, such as cell cytoplasm. Eosin is an example. There are also *neutral dyes* using another type of system, such as physical impregnation, to stain tissues.

Tissue components that react with alkaline dyes are called *Basophilic dyes*, whereas components or structures reacting with acid dyes are called *Acidophilic dyes*.

Also available are other dyes called metachromatic dyes, which show *Metachromasia* when staining. They include toluidine blue and thionine. Metachromasia is the property by which, when dyes get fixed to determined tissue structures, these structures become stained in a different color other than their own. This happens because the staining molecule polymerizes when it comes into contact with certain polyanion-rich tissue parts. The resulting polymer has light absorption properties different from those of the original molecule. These cell or tissue structures that are dyed differently with metachromatic dyes are called chromatropes. For example, if toluidine blue was used as metachromatic dye, the result would be a tissue mostly dyed blue, and certain structures such as mast cell granules, or the fundamental matter of cartilages could be purple dyed.

Dyes have different *means of action* when it comes to fixing into tissues. The means may be *physical* in which the solvent acts as a mode of transport for the dye molecules that are more soluble in the tissue than in the solvent. This is normally the most characteristic course of action in fat staining. Another case is based on great volume dye molecules selectively depositing, forming insoluble molecular aggregates on certain structures, and becoming trapped in the tissue, within the net of fibers and cells. This is the case of silver impregnation.

Chemical methods are based on the appearance of a chemical reaction between the structure which is the object of the staining, and the dye itself, resulting in a new chromogen. These methods are unique to histochemistry.

Physicochemical mechanisms are based on unions between molecules due to their electrostatic charge. Molecules with different charges unite. Stainings where acid structures join alkaline dyes, and alkaline structures join acid dyes are based on this mechanism, as it has previously been discussed for basophilia and acidophilia.

Generally, when we dyed our samples, we found that the vast majority of dyes are water-soluble. The cut obtained from the paraffin block is embedded in this substance, which is not

water miscible. Thus, in order to stain the samples, they need to undergo a process in which all the paraffin is removed from the cuts, and the tissue is then left in an aqueous medium. Such process is called *Deparaffinization*. It is the antagonistic process to the one suffered by the sample when it was embedded in paraffin. It basically includes the same elements but in the opposite order. Therefore, the samples will first be subject to successive baths in xylene, which will remove all paraffin from the tissue. The samples can be introduced for a few minutes in a heater at 60°C to help in this process, as this will turn the paraffin into a liquid state, and it will be more easily removed. After that, the sample will be bathed several times in absolute ethanol, to take the xylene away completely. Afterwards, the sample will be bathed again several times in ethanol 96% in order to hydrate the sample little by little. Then, the sample will repeatedly be bathed in running water. Some laboratories add more ethanol steps with decreasing concentrations before starting with water. But these two steps cited above are the strictly necessary ones, except in the case of an especially delicate sample.

Once our sample is stained, and before placing it under the microscope, the sample needs to undergo the *mounting process*. This process involves preparing the sample to be as clearly observable as possible under the microscope. And, at the same time, gives us the option to preserve the already stained sample for aftertime and successive observations. The easiest way to do that is by placing a coverslip on the sample. This is used for *in vivo* samples stained with vital dyes. These samples are not expected to last for a long time; they are prepared for a particular observation. Some stainings or techniques need mounting in an aqueous medium, because a different mounting would interfere with the staining, creating artefacts or impeding their observation. This is the case of fluorescence, and sometimes certain immune-histochemical products. In those cases, the sample is covered with a mounting medium such as gelatin or buffered glycerin, and a coverslip is placed on it. It is then sealed with lacquer to increase its durability. Even then, this type of sample has a very limited duration, since it is easily degraded. The *permanent mounting* of samples takes place in a resin medium, which apart from preserving, also improves the light refractive index, thus helping to achieve a better observation under the optical microscope. Nowadays, the most common method is to use artificial resins. But in the past, resins from trees such as Canada balsam or Dammar gum were normally used. These resins are not water miscible. Therefore, again, the sample will have to undergo a process in which water will be replaced with ethanol in an increasing concentration. And that ethanol will be followed by baths in xylene to remove the ethanol from the tissue, and prepare the sample for the resin. These baths in xylene are also called rinse. And once the xylene and ethanol are both totally removed, some drops of resin or mounting medium will be put on the sample, and a coverslip will be placed on it, preventing the formation of bubbles as far as practicable. When the resin is dry, the sample is then ready for observation under the microscope. And its durability is quite long.

Next, we proceed to describe some of the techniques most frequently used for studying liver biopsies.

Hematoxylin-Eosin Technique

This is one of the most used techniques in laboratory practice, both for clinical diagnosis and research. This technique is very adequate for a general vision of the tissue, which will show distinguishably nuclear staining, and cytoplasm staining. It is very simple, consists of only two steps, and is quick. Nuclear staining takes place through hematoxylin staining, cytoplasm staining, and the background eosin staining. Staining in these two dyes is based on

physicochemical methods. Therefore, to sum up, hematoxylin is basophilic and will stain acid structures in the tissue; eosin is acidophilic and will complement the process by staining alkaline structures in the tissue.

In the particular case of a *liver biopsy*, this technique is useful to assess the grade of preservation of liver structures, to detect Mallory bodies, and to assess cell ballooning.

The first part of the staining is made with hematoxylin, which is a vegetal origin dye extracted from logwood trees (*Haematoxylum Campechianum*) originating from Central America. A substance is extracted in the form of crystals that turn purple when they oxidize. This substance is used as a dye in the textile industry. These crystals have no staining capacities. They need to undergo an oxidation process to obtain a substance called hematein. This oxidation process can take place spontaneously when the crystals are exposed to atmospheric oxygen, or be induced by adding oxidizing chemical agents. Apart from these oxidizing agents, metallic salts are usually added, and they provide a greater staining capacity and a more specific affinity for acid structures, which are stained in the blue range of colors. Depending on the type of metallic salt used, different types of hematoxylin will be obtained: aluminum hematoxylin such as Harris' or Mayer's, iron hematoxylin such as Weigert's or Hedenhaim's, chrome hematoxylin, etc. each with its pros and cons. In our case, we used Carazzi's hematoxylin, since we have been very pleased with the results.

The second part of the staining is performed by Eosin, which is a xanthene dye obtained from the interaction of bromine with fluorescein, which contributes with its characteristic autofluorescence. As a result, there are two types of eosin: yellowish or eosin Y, and bluish or eosin B that differ according to the bromine atoms they contain. Eosin Y has a greater content, and is the one we chose to use. It shows staining affinity for cell and tissue alkaline structures, staining them in colors ranging from orangey to pink or red. It can be used both in water and alcohol solutions. In water solutions, it is necessary to add some type of substance protecting it from contamination, such as thymol or formol drops.

The reagents needed for this technique are:

Carazzi's Hematoxylin:

- 1 gram hematoxylin
- 0.2 grams potassium iodate
- 50 grams potassium alum
- 200 milliliters glycerin
- 800 milliliters distilled water

The reagents are added, in order, to a mortar in which they homogenize before the next reagent is added. In the end, a fine powder is obtained, which will then be slowly mixed with glycerin. Finally, water will be added, and the resulting mixture will be left for oxidation in contact with light and atmospheric oxygen for 15 days before use.

Watery Eosin:

- 5 grams yellowish eosin or eosin Y
- 500 milliliters distilled water

Some thymol will be added to the eosin solution in order to prevent its contamination.

The *technical procedure* is as follows:

- Dewax and hydrate the cuts.
- Introduce the cuts in Carazzi’s hematoxylin, from 10 to 15 minutes, depending on its maturation or oxidation state.
- Wash off in running water for 10 minutes, until the purple color of the cuts turns blue.
- Introduce the cuts in eosin for 30 seconds.
- Without washing, dehydrate, clear and mount with resin.

During dehydration of the samples, eosin also differentiates, thus removing its excess.

Results will show nuclei and nucleic acids in a range of blues, cytoplasm in orangey or pinkish, and cell structures such as collagen in pink. This way, staining will be useful for observing the general structure and the cell state of our liver biopsy.

Masson’s Technique

Masson’s technique is a trichrome stain designed for observing collagen fibers and connective tissue. In trichrome staining, dyes are normally intended for differentially staining various tissue structures. Thus, a nuclear stain, a cytoplasmic stain, and a collagen fiber stain will be used. Differential staining is founded, in part, upon the size of pores in various tissue components when the proteins reticulate as a result of fixation, which is much laxer in collagen structures than in cell cytoplasm structures. And it also partly depends on the treatment with phosphotungstic acid and phosphomolybdic acid underwent by the tissue to improve the affinity of collagen fibers for the dye.

This technique is of special interest in the case of liver biopsy for observing and assessing the degree of distribution of fibrosis.

If the samples have been fixed in formol, treatment with Bouin’s fixative solution is appropriate, since it will act as mordant for the next staining.

The *reagents* that used are:

Weigert’s Iron Hematoxylin

Solution A

- 1 gr hematoxylin
- 100 mL absolute ethanol

Solution B

- 4 mL ferric chloride at 29%
- 95 mL distilled water
- 1 mL hydrochloric acid

At the time of use, a working solution is generated by mixing solution A and B in equal proportions and well mixed.

Biebrich Scarlet and Acid Fucsin Solution

- 90 mL of Biebrich Scarlet in aqueous solution at 1%
- 10 mL of Acid Fucsin in aqueous solution at 1%
- 1 mL glacial acetic acid

Phosphotungstic Acid and Phosphomolybdic Acid Solution

- 5 gr phosphotungstic acid
- 5 gr phosphomolybdic acid
- 200 mL distilled water

Aniline Blue Solution

- 2.5 gr aniline blue
- 2 mL glacial acetic acid
- 100 mL distilled water

Acetic Acid Solution at 1%

- 1 mL glacial acetic acid
- 99 mL distilled water

The *technical procedure* is as follows:

- Dewax and hydrate the cuts.
- Wash off in distilled water.
- If the fixation has not been carried out with Bouin's fixative, perform a post-fixation with Bouin's solution for 12 hours at room temperature, or for one hour in a heater at 58-60°C.
- Wash off with abundant running water to remove all fixative remaining. Then wash off in distilled water.
- Dye with Weigert iron hematoxylin for 10 minutes.
- Wash off in running water for 10 minutes.
- Wash off with distilled water.
- Dye with the Biebrich Scarlet and Acid Fucsin solution for 15 minutes.
- Wash off with distilled water.
- Differentiate the cuts with the phosphotungstic-phosphomolybdic acid solution from 10 to 15 minutes.
- Dye with aniline blue from 5 to 10 minutes.
- Differentiate the cuts with the acetic acid solution at 1% from 2 to 3 minutes.
- Wash off in distilled water.

During the staining, we can control microscopically whether or not the phosphotungstic-phosphomolybdic acid solution has correctly differentiated and that the collagen fibers of the tissue do not appear red. If, after differentiation, the red color persisted, that means that the acid solution needs more time to act.

The *results* will show the nucleus dyed in black, muscle fibers, cytoplasm and keratin in red tones, and collagen fibers in deep blue.

Gomori's Reticulin Technique

This is a silver impregnation technique. This type of technique relies on silver salts that react with certain parts of tissues, normally electronegative structures that can attract silver ions. These ions, once fixed onto the structures, are forced to precipitate by means of the action of reducing agents, delivering a metallic silver pigment. Gomori's technique, more

precisely, is a two-stage silver impregnation that uses potassium hydroxide as the source and formol as the reducing agent. It uses potassium permanganate as oxidizing agent, potassium disulphite to whiten the cuts, and ferric alum as mordent.

The optimal result for this method depends in part on the wash that takes place before reduction with formol. Its duration should be determined empirically. It is also important to tone the samples with gold chloride. This gives a bluish grey color to precipitated silver, removes unspecific silver remnants, and gives collagen fibers a purple color.

With this technique in *liver biopsies*, as in previous cases, we observe and assess the distribution degree of fibrosis.

Neutral formol at 10% is recommended as the most adequate fixation. This technique can be used in paraffin, celoidine and freezing cuts. Cuts are recommended to be 6-7 microns thick, so as to allow for following the course of reticular fibers in tissue thickness.

The *reagents* that will be used are:

Potassium Disulphite at 2%

- 4 gr potassium disulphite
- 200 mL distilled water

Ferric Alum at 2%

- 4 gr ferric alum
- 200 mL distilled water

Ammoniacal Silver Solution

- 25 mL silver nitrate at 10%
- 5 mL sodium hydroxide at 10%

These two solutions are mixed, and ammonia is added drop by drop, until the silver precipitate is completely dissolved, and the resulting solution is completely transparent. To the consequential solution volume, an equivalent volume of distilled water is added. It is then filtered and let set for 12 hours in the dark. The excess of ammonia will evaporate. Once evaporated, this solution is preserved in a refrigerator at 4°C and protected from light.

Neutral Formol at 10%

- 20 mL commercial formalin
- 180 mL distilled water

The solution's pH is measured and then adjusted to pH 7, using a sodium hydroxide solution.

Gold Chloride at 0.2%

- 0.4 gr gold chloride
- 200 mL distilled water

Sodium Thiosulphate at 2.5%

- 5 gr sodium thiosulphate
- 200 mL distilled water

Neutral Red at 1%

- 2 gr neutral red
- 200 mL distilled water

The *technical procedure* is:

- Dewax and hydrate the cuts.
- Wash off with distilled water.
- Cover the cuts with potassium permanganate at 1% for 2 minutes.
- Wash off in distilled water.
- Whiten the cuts with potassium disulphite solution at 2% for 1 minute.
- Wash off thoroughly in distilled water several times.
- Treat the cuts with ferric alum at 2% for 1 minute.
- Wash off twice with distilled water.
- Treat the cuts with previously filtered ammoniacal silver solution for 1 minute.
- Wash off the cuts in distilled water for 5 minutes making several changes.
- Reduce the cuts with neutral formol at 10% for 5 minutes.
- Wash off thoroughly with distilled water.
- Treat the cuts with gold chloride solution at 0.2% from 5 to 10 minutes.
- Wash off in distilled water.
- Add potassium disulphite at 2% for 1 minute.
- Wash off in distilled water.
- Treat the cuts with sodium thiosulphate at 2.5% from 1 to 2 minutes.
- Wash off with distilled water.
- Optionally, stain once with neutral red at 1% as a nuclear stain acting as a contrast.
- Wash off with distilled water.
- Dehydrate, clear and mount in resin.

The *results* will show reticular fibers in black, nucleus in grey, and collagen in a light purple tone. If the sample has been contrasted with neutral red, then cell nucleus will appear black.

PAS Technique

This technique's name is an acronym for Periodic Acid Schiff, which is the main reagent in this histochemical technique. This technique is much used for determining mucopolysaccharides, glycoproteins, glycolipids, simple polysaccharides... Schiff reagent is obtained by modifying basic fuchsin treating it with sulphurous acid, thus making it lose its characteristic fuchsia color and turning it colorless. Then, when it reacts with carbonyl groups in the tissues, it retrieves its broken double bond and regains its fuchsia color.

Before using Schiff reagent, the technique requires that the tissue has previously been oxydated using periodic acid. This increases the amount of carbonyl groups present in carbohydrates, to make them more evident.

Nuclear staining is generally used as contrast with hematoxylin. In our case, we will use Carazzi's hematoxylin.

In the particular case of liver biopsy, this technique is useful for observing cell glycogen content, and assessing the degree of metabolic alteration suffered by hepatocytes. Hepatocyte content can also be observed in lipofuscin pigment, which is a brown color pigment that

appears in cell cytoplasm as a consequence of fatty acids degradation, and affects cell functionality.

The *reagents* that will be used are:

Carazzi's Hematoxylin

Periodic Acid at 2.5%

- 5 gr periodic acid
- 200 mL distilled water

Schiff Reagent

- 0.25 gr basic diamond fuchsin in crystals
- 6 gr sodium dithionite
- 300 mL distilled water

To elaborate, fuchsin is blended in a mortar and 150 mL distilled water is added. Separately, the sodium dithionite is mixed with the other 150 mL of distilled water. These are individually filtered, and then slowly mixed by pouring the sodium dithionite solution into the basic fuchsin one. The result will be a clear and opalescent solution that must be preserved in a refrigerator at 4°C and protected from light.

Sodium Disulphite at 2%

- 4 gr sodium disulphite
- 200 mL distilled water

The *technical procedure* is as follows:

- Dewax and hydrate the cuts.
- Treat the cuts with periodic acid at 2.5% for 10 minutes.
- Wash off in running water for 10 minutes.
- Wash off in distilled water.
- Dye the cuts with Schiff reagent for 15 minutes, preferably protected from light.
- Treat with sodium disulphite at 2% from 3 to 5 minutes.
- Wash off in running water for 10 minutes.
- Wash off in distilled water.
- Dye the cuts with Carazzi's hematoxylin for 5 minutes.
- Wash off the cuts in running water for 10 minutes.
- Dehydrate, clear and mount with resin.

The *results* will show the nucleus in blue, and the positive PAS material in the range of pink to fuchsia. Glycolipids, gangliosides and cerebroside, mucoproteins in general, neutral mucopolysaccharides, simple polysaccharides like glycogen or glycoproteins of the basal membrane, are all considered to be PAS positive substances. The lipofuscin pigment is also PAS positive.

Perls' Prussian Blue Technique

This is a technique destined for the detection of free iron ions in the tissue, as well as their deposits, such as hemosiderin. Hemosiderin is the deposits of ferric hydroxide that appear in cell cytoplasm or inside macrophages. They are usually the result of natural or pathological degradation of hemoglobin.

The *reagents* that will be used are:

Potassium Ferrocyanide at 5%

- 10 gr potassium ferrocyanide
- 200 mL distilled water

Hydrochloric acid at 5%

- 10 mL commercial hydrochloric acid
- 190 mL distilled water

Carazzi's Hematoxylin

The *technical procedure* is as follows:

- Dewax and hydrate the cuts.
- Wash off with running water.
- Treat the cuts with a potassium ferrocyanide solution at 5% and hydrochloric acid at 5%, equal proportions, for 20 minutes.
- Wash off thoroughly with running water.
- Dye the cuts with Carazzi's hematoxylin for 5 minutes.
- Wash off in running water for 10 minutes.
- Dehydrate, clear and mount with resin.

The *results* will show iron granules in light blue, the cell nucleus in dark blue, and cytoplasms in yellow.

Specific Techniques for Fats

When working to detect fats, their physicochemical properties must be taken into account, because they will limit the methodologies to be used with them in the laboratory. Lipids are water insoluble, but they are very soluble in certain organic solvents, such as ethanol, acetone, chloroform, toluene or xylene. This feature will prevent them from being embedded in paraffin, since the lipid material would get lost in the process. Therefore, embeddings can only take place in water soluble media, such as gelatin. As an alternative frozen cuts of previously embedded material can be used.

The most appropriate fixative for the lipid material is formol, because of its good results when fixing neutral fats. If calcium chloride is also added to it, results are even more improved. This is because calcium ions will make lipids be more stable, and formol will then be able to fix them more efficiently.

When dying, the technique will highlight the presence of homophasic lipid tissue, which is the one to be found in very specific locations in the cell, such as the cytoplasm, without being mixed with any other element. Heterophasic lipids are dispersed throughout the cell

territory, and they are mixed with other substances. It is very difficult to determine their presence.

The staining mechanism to detect these homophasic lipids is a purely physical mechanism, which has much to do with the solubility characteristics of lipids. It is based on the fact that the dye is better dissolved in the lipid than in the medium that will be used for the technique (it will normally be ethanol or acetone). Consequently, there is a trend for dye molecules to migrate from the solution used into tissue lipids. The longer the sample is exposed to the solution with dye, the more intense the resulting color will be. This is because molecules accumulate gradually in lipid deposits.

As a general rule, the solutions of these dyes specific for fats are not usually very stable. Therefore, when possible, it is recommended to make them at the time of use. When that is not possible, the best option is to store them in an airtight container, because instability could make the dye precipitate and then deliver false positives.

When we made these techniques, we selected the cryostat cut of tissue already fixed. We made cuts of 7 to 10 microns. The next explanations of procedures that follow will be made bearing in mind cuts of these characteristics. It also has to be taken into account that since these preparations are made with aqueous mounting, their life is very limited- no more than 15 days if they are conserved at 4°C in a refrigerator.

Sudan IV Technique

This dye is specific for neutral fats. Special care will be required, since the dye precipitates very easily. Carazzi's hematoxylin will be used as a nuclear contrast dye, since in the Sudan IV technique there are only the lipids of the tissue, and contrast dye is very convenient to put them in context. This hematoxylin can be replaced by any other hematoxylin or by other nuclear dyes.

The *reagents* that will be used are:

Sudan IV Solution

- 1 gr Sudan IV solution
- 50 mL acetone
- 50 mL ethanol at 70%

The *technical procedure* is:

- Wash off cuts in ethanol at 70%.
- Treat the cuts with the Sudan IV solution for 10 minutes.
- Wash off with ethanol at 70%.
- Wash off in distilled water.
- Dye with Carazzi's hematoxylin for 5 minutes.
- Wash off in running water for 10 minutes.
- Without dehydrating, mount in an aqueous medium and seal with a lacquer.

The *results* will show the nucleus in blue, and lipids in a range from orangey-reddish to intense red.

Sudan Black Technique

This dye, as its name indicates, is black. Therefore, we recommend contrast dye for the nucleus with some dye such as neutral red, in order to help acquire a better general picture.

The *reagents* that will be used are:

Sudan Black Solution

- 1 gr Black Sudan solution
- 50 mL acetone
- 50 mL ethanol at 70%

The *technical procedure* is:

- Wash off cuts in ethanol at 70%.
- Treat the cuts with the Sudan Black solution for 10 minutes.
- Wash off with ethanol at 70%.
- Wash off in distilled water.
- Dye with neutral red for 2 minutes.
- Wash off in running water for 10 minutes.
- Without dehydrating, mount in an aqueous medium and seal with a lacquer.

The *results* will show lipids and myelin in black; and if a contrast dye has been performed with neutral red, the nucleus will appear in red.

Sudan Red or III Technique

This technique can also be used in paraffin cuts, bearing in mind that after the embedding process, the amount of lipids that will appear will be much lower than that of the tissue before the embedding process.

The *reagents* that will be used are:

Carazzi's Hematoxylin

Sudan III Solution

- 2 gr Sudan III solution
- 100 mL ethanol at 70%
- 100 mL acetone
- 2 gr Scarlet red

First, Sudan III solution is dissolved into the ethanol at 70%. Once it has been dissolved, acetone is added. And when it is homogeneous, it is dissolved again in Scarlet red. It is very important to thoroughly filtrate this solution before it is applied to the sample so as to prevent the formation of precipitates that could lead to false positives.

The *technical procedure* is:

- Dewax cuts and rehydrate with ethanol 96°.
- Wash off the cuts with ethanol at 50% for 1 minute.

- Treat the cuts with the Sudan III solution that has been previously filtered for 15 minutes in a heater at 60°C, or for 1 hour at room temperature.
- Quickly wash off the cuts in ethanol at 50%.
- Quickly wash off in distilled water.
- Dye the cuts with Carazzi’s hematoxylin for 5 minutes.
- Wash off in water for 10 minutes.
- Mount it in an aqueous medium and seal with a lacquer.

The *results* will show the nucleus in blue, and lipids dyed in red or orangey red.

Oil Red-O Technique

This technique can also be applied to paraffin cuts, bearing in mind that, as in the last case, most of the fats will get lost in the embedding process.

The *reagents* that will be used are:

Propylene glycol at 85%

- 85 mL commercial propylene glycol
- 15 mL distilled water

Carazzi’s Hematoxylin

Oil Red-O Solution at 0.5%

- 0.5 gr Oil Red-O
- 100 mL commercial propylene glycol

To prepare Oil Red-O, it is placed in a mortar and a small amount of propylene glycol is added. Then it must be blended and the sample homogenized by gradually adding the rest of propylene glycol. After that, the solution is heated to 95°C, while continuously stirred until the rest of stain is dissolved. Once it is hot, it is filtered with filter paper and left to rest all night through. The next morning, it will be filtered again through a glass-fiber filter with the help of a vacuum system. If the resulting solution is cloudy, a new filtration must be performed.

The *technical procedure* is:

- Dewax and hydrate the cuts.
- Wash off with propylene glycol at 100% for 5 minutes.
- Dye with the Oil Red-O solution from 48 to 72 hours.
- Wash off the cuts with propylene glycol at 85% from 1 to 2 minutes.
- Dye the cuts with Carazzi’s hematoxylin for 5 minutes.
- Wash off in running water for 10 minutes.
- Wash off several times with distilled water.
- Mount it in an aqueous medium and seal with a lacquer.

The *results* will show lipids in red color, and the nucleus in blue tones.

IMMUNOHISTOCHEMICAL TECHNIQUES

Immunohistochemistry is a process through which a specific antigen can be detected, amplified and visualized both at tissue and cell levels. This is achieved by means of the antigen-antibody reaction, which is very specific and of high affinity. In immunohistochemistry, selected antibodies are used to identify specific antigens. In immunohistochemistry, antigen is any substance or molecule that we want to detect. In order to visualize the site where the antigen-antibody reaction takes place, a tracker or marker is needed. Such marking can be done with fluorochromes (immunofluorescence techniques), with enzymes (immunoenzymatic techniques), with metallic ions in colloidal form (immunogold technique) or with radioactive isotopes. The antigen can be detected both through direct marking of the primary antibody (direct method), or indirectly using a secondary or even a tertiary antibody.

In order to better understand the technique and the antigen-antibody reaction, we will explain some basic concepts:

- *Immune response.* This response lays in the identification of a foreign agent. Such identification takes place through two types of molecules: T-cell receptors and immunoglobulins.
- *Antigen.* The substance or substances capable of producing an immune response, either humoral or cellular, or both at the same time (immunogenicity), capable of combining with antibodies and with cell receptors (antigenicity), and capable of producing an allergic reaction (allergenicity). Each antibody is specific for a determined antigen, and binds to a determined part of it, called epitome or antigenic determinant, thus establishing the antigen-antibody specificity.
- *Antibody.* The molecules with antibody activity are generically designated as immunoglobulins. All immunoglobulin molecules present a common structure composed of four polypeptide chains, two long chains (H or heavy chains) and two short chains (L or light chains). According to the primary structure of their heavy chains, they are divided into five classes, and are termed Ig G, Ig A, Ig M, Ig D, and Ig E.

Immunohistochemical Detection Systems

Direct Method

This is the simplest method, and involves only one step applying the specific antibody against the antigen that one wants to demonstrate. The antibody is conjugated with a marker (either fluorescent or enzymatic) that makes the reaction visible under the microscope.

Indirect Method

The first antibody is specific for the antigen that we want to demonstrate, and it is not conjugated with any marker. A second antibody has to be used (developed in an animal of a different species from the first). This second antibody can be marked or not (the second antibody is specific for the first antibody). If the second antibody is not marked, a third

antibody (developed in the same animal species as the first) is used. This third antibody is marked.

Types of Immunohistochemical Techniques

Based on the marker (fluorochrome, enzymes, etc.) and the detection system used (direct or indirect method), different types of immunohistochemical techniques can be found.

Immunofluorescence Techniques

Fluorescence is a form of luminescence, understood as the emission of light generated by a non-thermal energy source, and under the effect of an excitation. Primary fluorescence (autofluorescence) is that spontaneously presented by certain substances. In tissues that do not have this property, fluorescence can be induced (secondary fluorescence) through immunohistochemical techniques, using fluorescent molecules, named fluorochromes, as markers. Fluorochromes are chemical molecules that absorb light at a certain wavelength and deliver a different one. Their excitation spectrums and emissions vary according to the fluorochrome used. The most used fluorochromes in immunofluorescence techniques are: fluorescein, rhodamine, Alexa Fluor, DyLight Fluor, etc. The disadvantage of this type of technique is that it is not permanent marking, since the light emitted by the fluorescent molecule (fluorochrome) vanishes with time. Therefore, it must be preserved from light. In order to visualize the results of this technique type, a special microscope is necessary: fluorescence microscope.

Immunoperoxidase Techniques

In this technique type, peroxidase is the marker used. Peroxidase is an enzyme obtained from horseradish, and it is the most used enzyme tracker. Peroxidase can be used both bonded to the primary antibody (direct technique, the simplest method, but less sensitive for antigens detection) and in immunocomplexes called PAP (peroxidase+antiperoxidase antibody) that will join a bridging antibody (secondary antibody) in the indirect technique. These PAP complexes will be the tracers for the antigen-antibody reaction. Next, the marker will be developed by oxygenated water (H₂O₂) added as substrate, together with the chromogen appropriate for that enzyme. The reaction takes place when the enzyme binds to the substrate, releasing oxygen, thus causing the chromogen oxydation and originating an insoluble brown product. Peroxidase can be endogenously found in tissues.

Techniques with Alkaline Phosphatase

When tissues are very rich in endogenous peroxidase, alkaline phosphatase is used as the tracer. Sometimes, there is endogenous phosphatase but in a few number of tissues than in normal conditions. In these cases, its endogenous activity requires no inhibition. If needed, it can be inhibited with levamisole. This enzyme is developed using Naphthol-AS-MX phosphate as a substrate, and Fast Red TR or Fast Blue BB as chromogen.

Avidin-Biotin Technique

This type of technique uses biotinylated antibodies. Biotin is a low molecular weight vitamin presenting a high affinity for avidin. Avidin is a high molecular weight glycoprotein that can be found in egg white and in the *Streptomyces avidini* bacteria (streptavidin). An almost irreversible and very rapid interaction takes place between them. Avidin has four connection points with biotin, and can be conjugated with different markers. Its specificity and affinity are much greater. It can be developed by the DAB, if the marker used is peroxidase.

Immunohistochemistry Universal Kit

Currently, there are several universal kits containing all the reagents required in the immunostaining process. Some of them even allow for indiscriminate use with monoclonal and polyclonal antibodies, and enable their development in different colors, choosing the adequate marker and chromogen. Most of these kits use indirect detection systems based on polymers. An important advantage of this detection system is that it normally is ultrasensitive with the associated primary antibody saving.

Immunohistochemistry Techniques Processes

All immunohistochemistry techniques follow a similar process. The differences that may exist in such processes are normally caused by: the type of study sample, the type of tissue used, the fixation system used, whether the sample is embedded or frozen, the embedding media used, the primary antibody to be used, the detection system, and the selected development system. The following scheme shows a summary of the process to follow, which will be discussed later.

1. Deparaffination and hydration of previously identified samples.
2. Antagonist unmasking if necessary.
3. Washout.
4. Enzymatic activity blockade.
5. Washout.
6. Background staining blockade.
7. Primary antibody incubation.
8. Washout.
9. Detection system.
10. Washout.
11. Development system.
12. Washout.
13. Counterstaining.
14. Washout.
15. Dehydration and mounting.

The entire process has to be carefully performed, avoiding whenever possible, interfering or destroying the tissue and cell structure, and conserving its immunoreactivity. All variables in the process affect the outcomes of the immunohistochemistry technique used. The loss of antigenic epitope integrity depends on them.

Fixation

For this process, sample fixation is one of the most important steps. The ideal fixative in immunohistochemistry preserves the antigens' integrity, preserves tissue and cell morphology, prevents the extraction, diffusion or displacement of antigens during the fixation process, and does not interfere with the antigen-antibody reaction. There is no universal fixative. It has to be chosen from among the antagonist groups that one wants to demonstrate. The most used fixative is formaldehyde or formalin (aqueous solution of formaldehyde). It is prepared at 10% starting with commercial formol (formaldehydes at 40%), which gives the solution a final formol concentration of 4%. This fixative generates reticles, creating bonds or cross-linked bridges, and giving as a result a net in which epitopes are masked and the primary antibody is prevented from binding the antigen.

Deparaffination and hydration of Samples

Once the cuts have been rehydrated, it is very important to prevent them from drying out, because when cuts dry in any of the technique's steps, an unspecific staining may take place. To avoid that, the immunostaining process is performed in trays or metallic containers called moist chambers. This helps the cuts remain hydrated and prevents evaporation. A PAP pen can also be used. This is a special marker that creates a fine hydrophobic layer around the cut, which helps dilutions remain exclusively in the regions of interest and maintains the cuts hydrated. It also helps saving antibody.

Antigen Unmasking (For Tissues Fixed in Formol)

Antagonist recovery is the process through which the antigen's molecular structure is restored, and immunoreactivity is retrieved, thus providing optimal immunohistochemical results. The methods used to obtain an antagonist recovery are:

Enzyme Unmasking

Proteolytic enzymes are normally used with proteinase K, trypsin, pepsin, pronase, etc. These enzymes facilitate the tissue penetration of antibodies, eliminating the protein net that wraps antagonist determinants through the fixation process. This method will depend on: enzyme type and concentration, time and temperature of digestion, tissue type and fixation type. Therefore, the digestion time should be adjusted to each case.

Heat-Induced Unmasking (Heat-Induced Epitope Retrieval-HIER)

Most antibodies used in tissue that has been fixed with formol and embedded in paraffin, then require this method for antigen retrieval. Variables with a greater influence on HIER effectiveness include: temperature, time, tissue fixation time, nature and pH of the retrieval buffer. HIER is normally performed through incubation in a citrate buffer or EDTA, at a temperature of 97°C-98°C for 20 minutes. Domestic microwaves or pressure cookers are frequently used for this. But the best option, when available, is to use a scientific microwave, which, unlike previous options, allows for accurately controlling time and temperature.

Enzyme Activity Blockade

This is a method to achieve enzyme activity inhibition for the enzyme used as a marker that can be endogenously found in the tissue. The method involves the incubation of the cuts before the immunological process, applying an agent that blocks in each specific case. If the blockade is not performed, false positives could be obtained in the immunostaining.

Background Staining Blockade

Background staining can be specific or nonspecific. Specific staining can be due to the presence of the study antigen in locations different from those where it was expected to be detected, the existence of antibodies in the primary antiserum acting against different antigens than those expected to be determined, or the passive trapping of antigens, or antigen diffusion, to places where they are not normally found. The most common nonspecific staining is the non-immunological bond of the antibody with certain tissue components, due to hydrophobic and electrostatic forces. The blockade solution binds to binding sites that are not specific inside the tissue, aiming at preventing the nonspecific bonding of primary and secondary antibodies. Cuts are incubated with a protein solution, such as bovine serum albumin (BSA) or normal serum of the same animal species as the secondary antibody. With the objective of ensuring the technique's specificity, an adequate dilution of the primary antibody needs to be achieved, preventing evaporation during incubation, and making the washes be thorough.

Primary Antibody Incubation

Depending on the chosen primary antibody, the corresponding manufacturing company will provide specific indications on its dilution ranges, time and temperature for incubation, detection method, etc. These vary based on the following: type of antibody used, detection method to be used, and whether the tissue used is embedded in paraffin and fixed in formol.

There are two types of antibodies, monoclonal and polyclonal antibodies.

- *Monoclonal* antibodies can be created in mice or rabbits. They are the product of a single clone of plasma cells. Therefore, antibody molecules are all immunohistologically identical, with only one specificity and only one affinity.
- *Polyclonal* antibodies are the mixture of immunoglobulins synthesized by different plasma cell clones that react with different epitopes on the antigen for which they were created. When the optimal dilution of primary antibody has to be determined, titration is needed. Antibody titration is the higher dilution of an antibody, resulting in the maximal specific coloration with the minimal background. It is performed through serial dilutions of an antibody stock solution (1/25; 1/50; 1/100; etc.). The habitual incubation time is one hour at room temperature, 30-60 minutes at 37°C, and 12 hours or more in a refrigerator at 4°C.

Detection Systems

In order to make the antibody-antigen union visible under the microscope, it is necessary to use detection and coloring systems. Several types of detection systems can be found. Some of them have already been discussed here.

Development Systems

These development systems are based on the enzyme-substrate reaction. Detection systems use enzymes to transform colorless chromogens into colorful final products as a result of oxidation. This allows for their visualization under the microscope. The most used enzymes are peroxidase and alkaline phosphatase.

Counterstaining or Contrast Staining

Counterstaining is normally used to facilitate the visualization and detection of immunostained tissue areas, distinguishing them from those areas that are not stained. This contrast staining is usually carried out with hematoxylin.

Dehydration and Mounting

Dehydration is achieved through washes in alcohols of increasing concentrations to take the cuts to xylol. The mounting used can be aqueous or permanent, depending on the chromogen type used, and on whether the resulting color product is soluble or not in alcohol and in other organic solvents.

Washes

Throughout the process, several washes are required between subsequent steps. They are performed in order to remove the excess of primary antibody and of other products used during the process. Washes are normally performed with buffered solutions to which a detergent (Triton X-100, Tween 20, etc.) is added. This detergent acts to permeabilize membranes and helps antibodies penetrate adequately and reach the antigens to be detected. Several washes of short duration (5 minutes) are usually more effective than one single longer wash. Given the large number of washes required, some cuts are frequently peeled off. Therefore, using an adhesive is recommended to fix cuts to the slide, with adhesives such as egg albumin, gelatin or poly-L-lysine. It is important not to add too much adhesive, since non-specific background staining could increase.

Controls

Controls are carried out in order to check whether the immunohisto-chemical technique performed is specific, and verify that there are no false negatives or positives.

Negative Controls

An omission of the primary antibody or its replacement by non-immune serum or buffered solution. The same tissue as for the positive control is used. If the results are positive, this will be due to an unspecific fixation.

Positive Controls

These are performed using a tissue cut including the antigen to demonstrate. If the result is negative, the cause is a fixation defect or an error during the technique procedure.

Automated Immunostainers

Thanks to new technologies, devices that perform automatic immunostaining can be found nowadays. They allow for the introduction of slides with tissue cuts, previously tagged

with barcodes for their identification using a reader, and each sample will be applied with the correct reagent. This process is very laborious due to the precision required on each of the samples, and due to the complex electronic mechanism controlled by a computer, which comprises its own thermal source for the antigenic unmasking. This involves a great progress with a reduction in errors while the technique is performed, since times, temperatures, reagent quantities, etc. are not shortened nor exceeded.

Chapter 308

CONVENTIONAL IMAGING TESTS FOR THE EVALUATION OF NASH

***Luis Tomás Ocaña Wilhelmi, MD, PhD,
Bruno Ramos Molina, PhD***

and Enrique Glückmann Maldonado, MD

Surgery Department, University of Málaga, Málaga, Spain

ABSTRACT

In the last two decades, enormous progress has been made in the evaluation of NAFLD by non-invasive images, techniques that receive more and more attention. Among these stand out (in addition to others in research that use biological markers and image): Ultrasound, Computerized Tomography, Magnetic Resonance Imaging (PDFF), Magnetic Resonance Spectroscopy, Magnetic Resonance Elastography, Transient Elastography (VCTE, CAP) and ARFI/SWE (Impulse Acoustic Radiation Force/Share Wave Elastography).

The diagnosis is important since it has proven that bariatric surgery is not only cost effective in cases of advanced fibrosis (f3), but also for obese patients with NASH, independently of the stage of fibrosis. Therefore, we must differentiate from the beginning the usefulness of these tests in the three diagnostic spectra of this disease: those that detect steatosis well, its evolution to NASH and fibrosis.

There are so many tests nowadays that are offered for the determination of steatosis and/or fibrosis of our patients, which will have to be adapted to each Center and to speak with the Hepatologist and the Radiologist when evaluating this disease in the best way possible. Thus, depending on the experience and availability of material they have, we may find variability among Hospitals regarding the imaging methods and biomarkers used in the diagnosis of NAFLD/NASH.

Keywords: Conventional Ultrasound (CUS), Computerized Tomography (CT), Magnetic Resonance Imaging (MRI, PDFF), Magnetic Resonance Spectroscopy (MRS), Magnetic Resonance Elastography (MRE), Transient Elastography (VCTE, CAP) and Impulse Acoustic Radiation Force/Share Wave Elastography (ARFI/SWE)

INTRODUCTION

The NAFLD and its evolution to NASH and later Fibrosis, which is complicated with Cirrhosis, Hepatic Failure and Hepatocarcinoma, that requires a transplant or end in the death of the patient, will shortly become one of the most prevalent diseases and that more resources health will need. Of course, it is the most common form of liver disease today [1, 2] affecting 80-100 million people in the United States [3]. We have arrived at this because of the pandemic that is Obesity, and the diseases that are related to it and that make up the Metabolic Syndrome, which as a pernicious vicious circle do nothing but feed back and take the patient to a point of no metabolic return.

The European Clinical Practice Guideline (EASL, EASD, EASO) for the management of NAFLD precisely defines this disease from the point of view of biopsy and image, which is the objective of this chapter. Thus, NAFLD is a mild condition that is characterized by excessive accumulation of liver fat (presence of steatosis in more than 5% of hepatocytes). This percentage is calculated according to the histological analysis or a fat fraction of proton density (providing an approximate estimate of the volume fraction of fatty material in the liver) greater than 5.6%, evaluated well by magnetic resonance spectroscopy of protons (^1H -MRS) or by selective magnetic resonance of fat/quantitative water (MRI) [4].

As the clinic is silent, if we do not think about it we will not be able to make the diagnosis, which is not indicated in the general population, but in obese or diabetic patients and who are at risk of liver disease. To make the diagnosis, we will begin with the imaging tests, where MR is the most accurate to determine the volume of liver fat, but it is expensive and not available to all centers. Ultrasound is cheaper and accessible, but it has its limitations. Regarding the biological markers, we still do not have one that is totally reliable in the diagnosis of NASH, so we have to continue investigating, as well as in the different tests available [5]. Finally, we must continue to perform liver biopsy, an authentic gold-standard for the diagnosis of NASH, in patients at risk, either because they already have advanced disease or because of the more than predictable evolution to it.

The key to diagnosis is, therefore, in the non-invasive evaluation. Non-invasive markers should aim to: in the field of primary care, identify the risk of NAFLD in individuals with a high metabolic risk; in the field of secondary and tertiary care, identify individuals with a worse prognosis, for example, those with a severe NASH; monitor the progression of the disease; and predict the response to therapeutic interventions. If these objectives are achieved, the need for liver biopsies could be reduced [4].

Therefore, when a physician sees a patient with non-alcoholic fatty liver disease (NAFLD) in a clinical setting, three general clinical questions arise, which attempt to respond with imaging techniques: does my patient have NAFLD?; Does my patient have a nonalcoholic steatohepatitis (NASH)?; and Does my patient have advanced fibrosis? [6]. We must also ask ourselves which technique is best for each event, if it is cost efficient and what are its limitations.

The need for screening for NAFLD in the general population is highly questioned due to several factors: the high direct and indirect costs of the tests to be performed, the low predictive value of non-invasive tests, the risks of liver biopsy and the lack of effective treatments [7]. However, the progressive form of NAFLD (NASH), particularly when associated with advanced fibrosis, should be identified in at-risk patients (age > 50 years, type

2 diabetes mellitus or MetS), due to its prognostic implications. Similarly, although a family grouping occurs, it is generally not advisable to detect the family, with the exception of cases with defined hereditary diseases, for example, lysosomal acid lipase deficiency [4].

In the last two decades, enormous progress has been made in the evaluation of NAFLD by non-invasive images, techniques that receive more and more attention [6, 8]. Among these stand out (in addition to others in research that use biological markers and image): Ultrasound, Computerized Tomography, Magnetic Resonance Imaging (PDFF), Magnetic Resonance Spectroscopy, Magnetic Resonance Elastography, Transient Elastography (VCTE, CAP) and ARFI/SWE (Impulse Acoustic Radiation Force/Shear Wave Elastography).

The available or developing imaging tests assess different properties of the tissue, including diffusion, texture, amount of fat, the amount of bonds in the fat and the stiffness of the liver [6]. Therefore it is important to know the pathophysiology of this disease to understand the new imaging techniques that are being developed and that associate the use of different biomarkers. These phenomena, together with the increase of cytokines and other substances, the damage of mitochondria, the different capacity of diffusion of gases by fatty particles, etc. have made possible the development of very promising techniques for the diagnosis of NAFLD and differentiate it from its progression to NASH.

The diagnosis is important since it has proven that bariatric surgery is not only cost effective in cases of advanced fibrosis (f3), but also for obese patients with NASH, independently of the stage of fibrosis [9]. Therefore, we must differentiate from the beginning the usefulness of these tests in the three diagnostic spectra of this disease: those that detect steatosis well, its evolution to NASH and fibrosis.

There are so many tests nowadays that are offered for the determination of steatosis and/or fibrosis of our patients, which will have to be adapted to each Center and to speak with the Hepatologist and the Radiologist when evaluating this disease in the best way possible. Thus, depending on the experience and availability of material they have, we may find variability among Hospitals regarding the imaging methods and biomarkers used in the diagnosis of NAFLD/NASH.

ECOGRAPHY

Ultrasound has always been used routinely in the preparation and study of our bariatric patients. And it is common for the radiologist to inform us of the presence of Fatty Liver, either with that term or with Hepatic Steatosis. Until now it was something like the “brand of the house” of every overweight patient. And it is because it is more accessible and cheaper than MRI, which is the benchmark.

Ultrasound has shown a sensitivity of 60 to 94% and a specificity of 84 to 95% in the detection of hepatic steatosis, being a first-line acceptable tool for the detection of steatosis in clinical practice, but cannot distinguish NASH of simple steatosis [8]. In addition, it does not reliably detect steatosis when it is <20% or in individuals with a high body mass index (> 40 kg/m²). Despite its dependence on the operator, ultrasound reliably diagnoses moderate or severe steatosis and provides additional hepatobiliary information.

In this procedure, radiologists review the conventional brightness in the B-mode ultrasound images of the liver and the surrounding structures and evaluate the

ultrasonographic characteristics known for fat content, such as the echogenicity of the liver in relation to the adjacent right kidney and darkness of Liver structures. From these qualitative characteristics, the presence and degree of hepatic steatosis can be inferred. The degree of steatosis can be reported using subjective terms (“mild, moderate, severe”) or more formally using the CUS (Conventional Ultrasound) ordinal score designed to coincide with the ordinal scores used by pathologists to classify hepatic steatosis in histology [6].

The main advantages of the CUS is that it is a device available in any center, very well tolerated and safe, that is not expensive and that can be done with ultrasound from any manufacturer. On the other hand, among the main limitations is that the interpretation of the echographic characteristics of each patient is qualitative. In addition, other factors interfere in the test result, independently of the presence of hepatic steatosis, such as the characteristics of the patient (BMI, other liver diseases) and the test itself (observer, instruments such as ultrasound, transducer, probe) [6, 10].

Recent studies have shown that quantitative ultrasound may be superior to conventional ultrasound in detecting hepatic steatosis [11]. Ultrasound has also been used in different scores and studies to identify fatty liver and NASH, given its hyperechogenic and bright pattern [12]. Due to the limitations of other non-invasive tests, conventional ultrasound continues to be the diagnostic modality most commonly used to diagnose and qualify hepatic steatosis [6].

COMPUTERIZED TOMOGRAPHY (CT)

The CT scan is rarely used to look for NAFLD. In general, it is an incidental finding in an abdominal CT performed for another indication. The density of the liver/spleen ratio is typically used to detect hepatic steatosis on computed tomography. However, these studies are not of first indication for the evaluation of hepatic steatosis, since they expose patients to ionizing radiation [6].

In general, it is similar to Ultrasounds, and as limitations it has hemochromatosis and it does not distinguish Steatosis from NASH, and, as we have said, it also produces radiations [10]. It has been used in some studies, such as one on the improvement that bariatric surgery entailed on fatty liver, in which CT scans were performed before and one year after surgery [13].

MAGNETIC RESONANCE IMAGE (MRI)

MR is considered the “gold standard” of imaging techniques [14] and the most accurate method for determining NAFLD. It is also superior to ultrasound to detect steatosis of lesser amounts. It qualitatively and quantitatively identifies the fatty infiltration of the liver thanks to the fact that water and fat protons produce different frequencies in a magnetic field. The most widely used quantitative method is the so-called phase and out-of-phase image processing, in which the signal of the fat protons is added or subtracted, respectively, from the signal of the protons in the water. This makes it an accurate predictor of liver fat content compared to histological evaluation [15].

The term PDFF (Fraction of Fat of Proton Density) indicates a fundamental property of the liver tissue and represents the function of triglyceride protons visible by MR in the sum of triglycerides and water protons, and manages to estimate the hepatic fat content without using the spectroscopy. And it has the benefit that it can obtain a complete image of the liver, locating the area where we are going to measure the infiltration, since the liver fat is heterogeneous and is not evenly distributed, varying from one segment to another [6].

While it is very good at providing quantitative information on the accumulation of fat in the liver and although many MRI techniques have been developed to improve its performance in the diagnostic spectrum of NAFLD, these methods are limited in their ability to detect the coexistence of inflammation or fibrosis. In addition, MRI is expensive, time consuming and movement artifacts, such as breathing, can affect the quality of the image [10].

MRI can detect the quantitative decrease of fatty infiltration in the liver after bariatric surgery and, therefore, could be a valuable tool to monitor NAFLD/NASH after the operation [16]. MRI-PDFF is also useful for evaluating the response to treatment in early-phase NASH trials [17]. It also avoids confounding factors and is unaffected by the field strength of the scanner, patient factors (age, sex, body mass index and etiology of liver disease) and concomitant liver abnormalities such as iron overload or necroinflammation [18].

As a novelty in the use of MR in the search for NASH, DeMILI Test has emerged, as an online diagnostic service that allows, from a standard abdominal MRI, to obtain a report on the presence of NASH and liver fibrosis in a patient. It is accessed through a web platform and is based on two image biomarkers, FIBROmri and NASHmri. And, although it is a method still under evaluation, it already offers encouraging results with average areas under the curve (AUROC) of 0.83 for NASH and 0.85 for significant fibrosis [19].

MAGNETIC RESONANCE SPECTROSCOPY (MRS)

It is today the technique of choice for the quantification of liver fat. In fact, and as we mentioned in the introduction, it is the one used in the European Guidelines for the definition of hepatic steatosis: fat fraction of proton density (providing an approximate estimate of the volume fraction of fatty material in the liver) greater than 5.6% [4]. With the right equipment and when the fat concentration is equal to or greater than 7.48%, it can be 100% accurate [20].

It consists of a very useful non-invasive technique that adds supplementary metabolic information to the anatomical anomalies that appear in radiological images of different diseases. It allows the evaluation, *in vivo*, of the molecular composition of the liver, and, although it fails in the detection of NASH, it has a high accuracy in the diagnosis of steatosis [8].

The precision of this quantitative method is achieved by separating the spectrum of the water curve from those of lipids and other metabolites, these curves expressed according to their resonance frequency measured in parts per million (ppm). But it has its limitations, since it requires specialized software, being also slow, complex and expensive. It remains, for all this, confined, at the moment, to research studies [10].

ELASTOGRAPHY OF MAGNETIC RESONANCE (MRE)

The search for a technique capable of differentiating steatosis from steatohepatitis seems to have found a possibility in Magnetic Resonance Elastography, in addition to other advantages. The fact that necroinflammation and fibrosis have similar effects could be the basis for differentiating NASH from NAFLD, but differentiates NASH from Fibrosis?. The limitation would be the excessive accumulation of iron [10]. It also seems that it would be profitable in the classification by stages of fibrosis, but, like other methods based on Magnetic Resonance, its availability is scarce in many centers, in addition to requiring an additional external validation [8].

The MRE, which was invented at the Mayo Clinic, is a non-invasive and effective method, which will require three stages to obtain results. In the first place, low frequency longitudinal waves, which deform the parenchyma, will be transmitted to the liver. These waves are transformed into transverse waves, called “cut or shear,” which generate the data that is duly recorded. And finally, the analysis of these data, whose measurement, like the Transient Elastography by US, is quantified in kilopascals and that the equipment presents in the form of images.

This technique has a good correlation with liver biopsy, which has been the reason for different meta-analyses [21, 22]. Thus, the efficacy of MRE in diagnosing fibrosis gave figures ranging between 0.87 and 0.99 under the AUROC curve, depending on whether it was stage of Fibrosis 1, 2, 3 or Cirrhosis, in both studies. And they concluded that the liver hardness measured by EMR increases with the degree of fibrosis. The higher the hardness, the more fibrosis [23].

On the other hand, it is superior on Transmission Elastography measured by Ultrasound, when it comes to achieving success, 94% in MRE over 84% in the US [24]. In addition, the volume of liver tissue that evaluates is much higher, being able to reach 250 cm³, compared to, at most, 20 cm³ of TE, reducing errors as heterogeneous as fibrosis may be, which makes the study be much more representative. Unlike ultrasound, Resonance Elastography is not affected by the presence of ascites or by the narrowness of the intercostal spaces [23].

But it remains the most important challenge to require this technique if it can differentiate steatosis from NASH [25]. Apparently it could do in the early stages of steatohepatitis, since the inflammation could have hardness similar to fibrosis. Thus, even in the absence of fibrosis, which in many cases can accompany necroinflammation from the beginning, MRE could have its usefulness in the early diagnosis of NASH.

Finally, an additional advantage of this method is the ability to perform a “multiparametric” scanning protocol by associating in the same session not only the study of fibrosis, but also the accumulation of fat or iron, adding other MR sequences. And although other authors find that this technique does not have the limitation of body mass, others believe that excessive obesity, together with the inability to sustain apnea, claustrophobia and biliary obstruction, can make testing difficult.

TRANSIENT ELASTOGRAPHY CONTROLLED BY VIBRATION (VCTE)

Transient Elastography (FibroScan, Echosens, Paris, France) is a good tool for the calculation and non-invasive staging of Liver Stiffness Measurement (LSM). It will use the principles of ultrasound, applying low frequency cutting waves created by a vibratory probe at the level of an intercostal space that covers the liver. The elasticity, expressed in kilopascals, is determined by the elastic modulus calculated from the cutting wave velocity of the ultrasound signals.

The stiffness of the liver is determined with the value resulting from having made the calculations of the median of the 10 determinations made when applying the probe on the skin between the ribs of the patient, in the right part of the liver. Your measurements will place the patient at a certain level or degree of Fibrosis, which will have diagnostic implications, follow-up and, of course, treatment, being the average value for healthy people of 5.5 kPa.

When it is a value lower than 7 kPa it means that the level of progression is low, and it is recommended not to start with the treatment. Values between 7 and 9.4 kPa are evidence of moderate fibrosis or also called “level 2,” and the patient should be tested with fibroscan regularly. Values between 9.4 and 12 kPa mean that the fibrosis is progressing and is “level 3,” and with this result it is necessary to start treatment. When it exceeds 12 kPa, it means that the patient suffers from severe or “level 4” fibrosis, on the threshold of cirrhosis. This result indicates that the treatment or therapy is of an emergency nature.

Regardless of the cause that causes fibrosis, the mean areas under the curve (AUROC) were 0.84, 0.89 and 0.93 for the diagnosis of significant fibrosis, severe fibrosis and cirrhosis, respectively [26]. When the technique is analyzed in a wide series of cases and its comparison with the liver biopsy, it appears especially successful in the detection of more advanced fibrosis, such as F3 and F4, and with a moderate precision for the initial stages of fibrosis (F2). It is therefore a good method to differentiate advanced stages of hepatic fibrosis, compared to early stages [27].

It seems that obesity would be an adverse factor for the effectiveness of this technique, already with BMI above 28%. Therefore, to the conventional probe that reaches a depth of 25-65 mm (M-probe), a deeper probe (XL-probe) has been added that reaches up to 35-75 mm. Another adverse factor is the area analyzed, less than in other imaging techniques such as CT and any modality of MR, which analyze the entire liver. Likewise, situations such as necroinflammation of hepatocytes, cholestasis, elevated central venous pressure and postprandial conditions, can detract from this technique [10].

The greatest application that this method can contribute to the study of NAFLD would be to avoid performing liver biopsies, which according to the works could range from 45% of patients [26], to 60 or even 90% if fibrosis is more advanced. At a fixed sensitivity, a cut LSM of 6.5 kPa excluded advanced fibrosis with a negative predictive value of 0.91, and a cut LSM of 12.1 kPa excluded cirrhosis with a negative predictive value of 0.99 [27].

Finally, the Controlled Attenuation Parameter (CAP) is nowadays used as a tool that can be useful in the assessment of liver fat. It is available in the latest devices for measuring the rigidity of the liver controlled by vibration (VCTE). The most current studies show that it can be used to detect hepatic steatosis, although it does not provide a reliable quantitative estimate of the liver fat content [6].

ARFI/SWE

ARFI is the Impulse of Acoustic Radiation Force. It is a form of elastography that calculates the elasticity of the liver from acoustic pulses of short duration of a fixed frequency directed to a region and is expressed in KPa. It is good for patients with very high BMI, even above 40 klgr/m2 [10]. Other authors suggest that the use of VCTE in combination with ARFI is highly specific to predict significant fibrosis and may decrease the need for a liver biopsy.

The SWE (supersonic images of cutting waves) is a new technique of ultrasound elastography that has been used for the assessment of liver fibrosis. It has the advantage that being an evaluation in the form of a fan will value a larger region of the liver. It has also been used in the assessment of different chronic liver diseases, being superimposable to other elastographic techniques, such as VCTE and ARFI, and how they are fast, reliable and simple. But it has not appreciably evaluated steatosis in patients with NAFLD [10].

We can conclude by stating that ARFI is a promising image modality to detect advanced fibrosis in patients with liver disease related to obesity. And there are authors who believe that SWE and ARFI provide a better and more reliable estimate of liver fibrosis than VCTE [6].

MONITORING AND CONTROL

When deciding which is the best follow-up for our patients, we must take into account many aspects. Both the risk that the liver disease may progress to cirrhosis, and the workload of all specialists related to the disease, as well as the cost of imaging procedures, are issues to consider. Perhaps for all this, to date, there is no consensus on what would be the best follow-up protocol for these patients. What is agreed is that the surveillance of these patients should include routine biochemical parameters, noninvasive evaluation of fibrosis (imaging techniques, among others) and study of associated comorbidities.

Thus, patients with NAFLD who do not have worsening of their metabolic risk factors, that is, who are stable, should be monitored every 2 or 3 years. However, the control should be annual in those patients who have NASH or Fibrosis. And every 6 months if the evolution of the disease has reached cirrhosis. In these cases, and on an individual basis, the repeat of the biopsy at 5 years may be indicated.

COMPARISON OF THE DIFFERENT TECHNIQUES

Table 1. Efficacy of the imaging tests in the detection of Steatosis, NASH and Fibrosis

Chapter 309

MR SPECTROSCOPY AND QUANTIFICATION OF INTRAHEPATOCITARY LIPID CONTENT

Jaime Ruiz-Tovar*, MD, PhD and ***Carolina Llaveró†***

Obesity Unit, Garcilaso Clinic, Madrid, Spain

ABSTRACT

Currently, the standard procedure used to evaluate hepatic steatosis is the liver biopsy. This is an invasive practice that presents inherent risks. Increasing evidence suggests that Magnetic resonance imaging (MRI) and MR spectroscopy (MRS) may represent an accurate method to determine the hepatic lipid content.

In this chapter we will review the actual evidence about the use of MR spectroscopy to evaluate liver steatosis and non-alcoholic fatty liver disease (NAFLD).

Keywords: liver steatosis, magnetic resonance, spectroscopy, percentage of lipid content

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is characterized by lipid deposit in the hepatocytes of the liver parenchyma, exceeding the 5% of the liver weight. NAFLD includes a spectrum of disorders ranging from simple steatosis, a relatively benign condition, to nonalcoholic steatohepatitis (NASH) and pericellular or perisinusoidal fibrosis. In some cases, these entities might lead to a cirrhosis stage, similar to the observed in alcoholic hepatitis. The mechanism of NAFLD is still unknown, but involves the development of insulin resistance, inflammatory cytokines and oxidative stress [1, 2].

NAFLD is strongly associated with obesity, mainly with central one, and has become the most common liver disorder in Western countries [3]. The prevalence of NAFLD, in any degree, is estimated around 70% in obese subjects and up to 95% in morbidly obese patients

† Carolina Llaveró, RN.

[4]. Among patients undergoing bariatric surgery, liver steatosis is the most common degree of the disease, appearing NASH in about 25% of the cases and cirrhosis in 1-3% [5].

The diagnosis of NAFLD is usually made after an incidental discovery of unexplained elevation of liver enzyme levels or when steatosis is observed on imaging. Currently, the standard procedure used to evaluate hepatic steatosis is the histopathological examination of cross-liver sections and the semi-quantitative estimation of the percentage of hepatocytes containing macrovesicular fat. This is an invasive practice that presents inherent risks [1]. Despite there are several series in literature with an elevated number of patients undergoing a liver biopsy during bariatric surgery, without showing any morbidity related with the biopsy [6], for posterior monitoring of the liver status it is necessary to perform a percutaneous liver biopsy, implying an invasive procedure. Moreover, histological examination of cross-liver sections and the determination of the percentage of hepatocytes containing macrovesicular fat, only provides a two-dimensional estimation of a particular biopsy and is subject to inter-individual visual evaluation depending on the pathologist's training, which usually results in overestimation of the liver fat content [7, 8]. Therefore, it is essential to establish new non-invasive approaches to accurately determine the hepatic fat concentration, allowing the correct diagnosis and monitoring of steatosis.

The liver cell injury and intra-hepatocellular accumulation of lipids can be also evaluated by noninvasive tests. Increasing evidence suggests that Magnetic resonance imaging (MRI) and MR spectroscopy (MRS) may represent an accurate method to determine the hepatic lipid content, comparable to the liver biopsy to measure and follow up the fatty liver disease. Thus, they have been postulated as potential screening tools for patients at risk of liver steatosis, such as morbidly obese patients [8].

MRI represents a potential non-invasive technique for assessing hepatic steatosis in three-dimensions. MRS is a suitable method to quantify hepatic lipid content, as the values obtained by MRS are directly related to the molecular triglyceride content [9, 10]. One of the main advantages of using spectroscopy instead of biopsy is that it can be performed contemporaneously with MR imaging and the sampling volumes are larger than the obtained in liver biopsy avoiding misinterpretations if the fat liver distribution is heterogeneous [11, 12].

LIVER STEATOSIS AND BARIATRIC SURGERY

Bariatric surgery achieves an improvement or even complete resolution of NAFLD in morbidly obese patients. This fact has been demonstrated after Roux-en-Y gastric bypass (RYGBP), adjustable gastric banding and malabsorptive procedures (duodenal switch and biliopancreatic diversion) and sleeve gastrectomy (SG) [5, 13-16].

Liver steatosis regression has been associated with an improvement in the lipid profile, which is more likely to occur after malabsorptive techniques. However, a study of our group demonstrated a significant reduction of triglyceride levels and an increase of HDL-cholesterol 12 months after undergoing a sleeve gastrectomy, achieving both parameters values within the normal range. Therefore, an improvement of liver steatosis was observed, as expected. Our results were similar to those reported after Roux-en-Y gastric bypass (90-95% of resolution of the steatosis) [17, 18].

MR IMAGING AND MR SPECTROSCOPY

The MRI protocol performed at our institution included preoperative evaluation 2 weeks prior to surgery and postoperative evaluation at 6 months Postoperatively.

Axial T1-wi dual gradient-echo (TR/TE, 122 ms/5-2 ms; flip angle, 80°; slice thickness, 6 mm; matrix 256 × 256). In addition axial breath hold three dimensional (3D) T1-weighted high resolution isotropic volume examination (THRIVE) (TR/TE, 4/2 ms; flip angle, 10°; reconstructed slice thickness, 2 mm; matrix, 256 × 256) was acquired for volumetric analysis.

Before spectroscopy, for a better voxel placement, fast T2 single shot TSE sequences (TR/TE, 611/100 ms; flip angle 90°, slice thickness/GAP, 9/0.9 mm) were acquired in coronal, sagittal and axial planes. MRS was acquired with the single-voxel technique, two voxels were located in different regions within the left and right hepatic lobes to provide a more generalized distribution of fat within the liver. The average voxel volume was of 30 x 30 x 30 mm and 20 x 20 x 20 mm for the voxels located in the right lobe and left hepatic lobe, respectively. The voxel was located avoiding blood vessels, the gall bladder, and fatty tissue. After volume-selective autoshimming, the spectra were obtained with a point-resolved spectroscopy (PRESS) technique (TR/TE/scans = 2000 ms/35 ms/64) without water suppression. Each spectrum consisted of 1,024 complex data points in the time domain with a spectral width of 2,000 Hz. Chemical shift was placed relative to the water signal intensity.

Spectra were analyzed offline in the time domain using the AMARES algorithm included in the MRUI software package as described previously. The relative lipid content was defined by following the formulae [19]:

$$RLC = S_{lipid} / (S_{lipid} + S_{water})$$

For volumetric analysis, manual volumetric segmentations of the liver were performed by manual tracing of the liver on volumetric sequences in the axial plane avoiding the gall bladder and main hepatic vessels at a dedicated workstation (Advantage Workstation, Version 4.3; GE Healthcare Europe, Buc, France).

Steatosis by MRS was determined as absent when detected percentage of lipid content (PLC) was lower than 5%, mild when lower than 10%, moderate when 10-30% and severe when >30%, as described in literature [20-23].

EVALUATION OF LIVER STEATOSIS AFTER SG, ASSESSED BY MR SPECTROSCOPY

Indication for undergoing SG was presenting a body mass index (BMI) ≥ 40 Kg/m² or BMI ≥ 35 Kg/m² with comorbidities. Patients presenting a daily alcohol intake of more than 20 g per day, chronic hepatitis B or C virus infection, hepatotoxic drugs intake or other known liver diseases, presence of pacemaker or any metallic implant not compatible with MR, and claustrophobia, are not evaluated with MR spectroscopy.

We performed a prospective observational study evaluating liver steatosis, as measured by MR spectroscopy in 23 patients undergoing SG, with a mean age of 47.6 ± 10.6 years and

a mean BMI 47.6 ± 6.7 Kg/m². Six months after surgery, MR spectroscopy was repeated. At that time, mean BMI 32.2 ± 5.1 Kg/m², with a mean excess weight loss of $68.2 \pm 18.6\%$.

Mean preoperative hepatic volume was 1999.9 ± 436.2 ml and 6 months after surgery the liver volume significantly decreased to 1568 ± 170.3 ml ($p = 0.005$). Mean preoperative percentage of lipid content (PLC) was $14.2 \pm 15.4\%$ and 6 months after surgery these values decreased to $4.3 \pm 3.2\%$ ($p = 0.007$). A significant reduction of steatosis grade was observed, with disappearance of preoperative steatosis in 54.9% of the patients. Six months after surgery, 91.3% of the patients did not present any grade of steatosis.

In our study, we observed a preoperative steatosis incidence calculated with MRS of 63.6%. This steatosis rate is similar to the one observed by some authors, though other reports have shown higher prevalence that could vary from 65 to 80%. The steatosis grade was probably lower among our patients, as all of them followed a strict preoperative diet and a weight loss of at least a 5% of their overweight was a necessary condition to undergo the sleeve gastrectomy as bariatric procedure. It has been demonstrated that establishing strict dietary treatments with a total caloric intake of less than 1000 kcal / day between 2 and 8 weeks before surgery, in order to maximize weight loss during this period of time, result in a reduction of the surgical risk. This weight loss is associated with a reduction of hepatomegalia secondary to liver steatosis. We have observed a positive correlation between hepatic lipid content assessed by MRS and hepatic volume, suggesting that the hepatic volume loss observed after surgery is related to the decrease in the hepatic lipid content, as it has been previously reported in patients undergoing bariatric surgery.

Alterations of AST and ALT are the most frequent conditions found in NAFLD in morbidly obese patients [2], similar to our results. Notwithstanding, Dixon et al. [24] reported that changes in aminotransferase concentrations seems not to predict changes in steatosis. In the same line, a recent study observed a significant reduction of steatosis after bariatric surgery, documented with liver biopsy, but without correlation with AST or ALT levels. In our series, we observed a correlation between liver enzymes and PLC in the preoperative determinations, but the decrease of liver enzymes or the postoperative values did not show any correlation with PLC decrease or postoperative PLC values. Liver steatosis rate in morbidly obese patients ranges between 65-80%, but steatohepatitis appears in only 25% of the case. Hepatocyte fat infiltration might lead to a certain degree of inflammation and cytolysis, but this is especially relevant in severe steatosis grades. Thus, in the preoperative determinations of our series, with more than 25% of patients presenting severe steatosis, more steatohepatitis would be present and therefore a correlation with liver enzymes is possible. Postoperatively, steatosis remains in few patients and just in mild grade with probably absence of steatohepatitis, preventing a positive correlation between both entities [1].

EVALUATION OF LIVER STEATOSIS AFTER RYGB, ASSESSED BY MR SPECTROSCOPY

A similar study to the previously reported one on patients undergoing SG, was conducted on patients undergoing Roux-en-Y gastric bypass. Inclusion and exclusion criteria were similar. 21 patients were included, with a mean age of 48 ± 10.6 years and a mean BMI of 47.1 ± 10.5 Kg/m². Six months after surgery, mean BMI was 31.7 ± 4.9 Kg/m² with a mean

excess weight loss of $69.3 \pm 17.7\%$. Preoperative percentage of lipid content (P^{LC}) was $13.3 \pm 10.4\%$, with a significant decrease up to $3.5 \pm 2.6\%$ after surgery. Preoperatively, 70% of the patients presented liver steatosis at any degree, while after surgery a complete remission of steatosis was observed in all the cases, excepting one patient with steatosis grade III, decreasing to a grade I [25, 26].

Comparing these results with those obtained after SG, these are quite similar, concluding equivalent results at 6 months after surgery.

LIMITATIONS OF MR SPECTROSCOPY

The knowledge of percentage of lipid content is relevant, so long it is part of NAFLD and is associated with the progression to NASH or even cirrhosis. However, the disappearance of liver steatosis after bariatric surgery does not necessarily imply the remission of NASH and even less the regression of cirrhosis. Thus, to evaluate these issues, MR spectroscopy is not probably the most accurate method. Serum biomarkers can be helpful, despite their value is still controversial. Liver biopsy remains the gold standard to assess NASH and its evolution after bariatric surgery.

CONCLUSION

After bariatric surgery, a significant reduction of liver steatosis is observed, as demonstrated by a statistically significant reduction in the percentage of intrahepatocitary lipids and liver volume, determined by MR spectroscopy and MRI. These imaging techniques can be considered as noninvasive, accurate methods for monitoring liver steatosis in morbidly obese patients undergoing bariatric surgery.

Chapter 310

BIOCHEMICAL MARKERS

Soledad García-Gómez-Heras*, MD, PhD

Department of Histology, Rey Juan Carlos University, Madrid, Spain

ABSTRACT

Liver biopsy, although “gold standard” for the diagnosis of NAFLD/NASH, has some limitations. Nowadays, biochemical markers are an alternative less invasive or noninvasive tests and have the important characteristics of diagnostic tests. They focus on the specific pathways involved in the progression of disease: hepatocyte death or apoptosis, inflammation, fibrosis and oxidative stress.

Keywords: NASH-disgnosis, NAFLD, biochemical markers, non invasive test

INTRODUCTION

The current “*gold standard*” for the diagnosis and stratification of NAFLD is liver biopsy. It can determine necroinflammatory activity, degree of steatosis, and extent of fibrosis. But liver biopsy has some limitations as we have exposed in the other chapter: sample size, bleeding, pain, etc. so it is a resource that cannot be used routinely.

With the increasing incidence of NAFLD, we need to do regular control for NAFLD progression, evaluation of hepatic steatosis, NASH and advanced fibrosis.

The knowledge of whether a patient has simple steatosis or NASH is very important prognostically. Patients with NASH can progress to cirrhosis and therefore should be more actively managed to try and prevent disease progression.

This situation has led to the search of alternative less invasive or noninvasive tests to assess NAFLD. Nowadays, biochemical markers have the important characteristics of diagnostic tests: good cost-effectiveness, ease, and reproducibility. Their presence and level

* Corresponding Author’s Email: soledad.garcia@urjc.es.

are not liver specific but they have been associated with pathophysiologic liver disease processes (Pepe et al. 2001, Ruiz-Tovar et al. 2019, Tsai et al., 2018).

Several biomarkers have been proposed for the evaluation of hepatic steatosis, the prediction and progression of NASH and significant/advanced fibrosis. Next we expose some.

LABORATORY DATA

They included platelet count, alanine aminotransferase (ALT), aspartate aminotransferase (AST), insulin and albumin levels, in order to analyze the following formulas:

- Hepatic Steatosis Index (HSI) = $8 \times \text{ALT/AST} + \text{BMI}$ (+2 if T2D yes, +2 if female)
- Liver Fat Score (LFS) = $-2.89 + 1.18 \times \text{Metabolic Syndrome (Yes: 1; No:0)} + 0.45 \times \text{T2D (Yes: 2; No:0)} + 0.15 \text{ Insulin in uU/l} + 0.04 \times \text{AST in U/L} - 0.94 \times \text{AST/ALT}$
- AST to Platelet Ratio Index (APRI) = $(\text{AST/ALT} \times 100) / \text{Platelets (10}^9\text{/L)}$
- Fibrosis-4 (FIB-4) = $(\text{Age (years)} \times \text{AST}) / (\text{Platelets} \times \text{ALT})$
- Non-alcoholic fatty liver Disease-Fibrosis Score (NAFLDFS) = $-1.675 + 0.037 \times \text{age} + 0.094 \times \text{BMI} + 1.13 \times \text{Diabetes (Yes: 1; No:0)} + 0.99 \times \text{AST/ALT} - 0.013 \times \text{Platelet} - 0.66 \times \text{Albumin}$.

BIOMARKERS FOCUS ON THE SPECIFIC PATHWAYS INVOLVED IN THE PROGRESSION OF DISEASE

Biomarkers Focus on Hepatocyte Death or Apoptosis

- Serum Cytokeratin 18 (CK18) levels.

Describe initially by Feldstein et al. in 2009, reporting circulating serum levels of CK-18 to be predictive of NASH in patients with NAFLD. It is by far the one that has been the most widely investigated (Castera et al., 2019).

CK18 fragments are major intermediate filaments of hepatocytes. CK-18 fragments come from apoptosis of hepatocytes accomplished by the enzyme caspase 3 and can be measured in serum by immunoassay.

Serum CK18 levels correlate with histologic changes and reflect severity of NASH. Studies have shown its high specificity for NAFLD and fibrosis (Cusi K, et al., 2104; Tsai et al., 2018).

- Fibroblast growth factor 21 (FGF21), showed greater association with disease progression (Shen J, et al. 2012).
- CK18-M65 (uncleaved CK18), with strong accuracy in predicting NASH (Younossi et al., 2008).

Markers of Inflammation

- Ferritin
- C-reactive protein (CRP)

They are nonspecific markers of inflammation that have been shown to be associated with NASH (Hui et al. 2004; Musso et al., 2011; Targher et al., 2006).

- Adipocytokines. They are associated with presence and severity of disease. Studies have shown that low levels of adiponectin and high levels of tumor necrosis factor- α (TNF- α) are associated with higher levels of liver damage (Jarrar et al., 2008; Hui et al., 2004 b)
- Interleukin-6 and interleukin-8. Some studies have shown that are strongly correlated with NASH (Abiru et al., 2006; Ajmera et al., 2017; Wieckowska et al., 2008).

Biomarkers of Fibrosis

- Serum aminotransferases, they are not useful in diagnosing fibrosis but levels often decrease when fibrosis worsens. An AST/ALT ratio greater than 1 has been shown to be predictive of fibrosis because of impaired AST clearance (Williams et al., 1988).
- Hyaluronic acid (HA) production increases in fibrosis and its clearance decreases in advanced liver disease. Studies have reported good correlation of high HA levels with advanced fibrosis. However, different cutoff values were used, rendering interpretation difficult (Hartley et al., 2006; Kaneda et al., 2006; Piperno et al., 1998; Suzuki et al., 2005).

Markers of Oxidative Stress

Measurements of serum markers of oxidative stress are difficult because of their volatile nature but they are of interest because oxidative stress contributes to the pathogenesis of NASH; oxidized low-density lipoprotein, malonaldehyde, and thiobarbituric acid reactive substances have been evaluated in predicting NASH but results have been conflicting (Yesilova et al., 2005; Chalasani et al., 2004).

None of the available biomarkers have high sensitivity and specificity able to differentiate NASH from simple steatosis but they provide important information that require a critical interpretation of the results. For this reason, the use of imaging tests further complements the information available. It is desirable to look for the ideal combination between biomarkers and imaging tests (ultrasonography, computed tomography, elastographic techniques, magnetic resonance) (Ruiz-Tovar et al. 2019).

ABSTRACT

Obesity is a complex, chronic, progressive, and pandemic disease directly associated with the development of NAFLD (NonAlcoholic Fatty Liver Disease), which is considered the commonest liver disease worldwide. In addition, NAFLD is recognized as a condition that may progress to end-stage liver disease like cirrhosis and/or hepatocellular carcinoma, bariatric surgery provides improvement or even histological resolution of NAFLD and NASH (NonAlcoholic SteatoHepatitis).

To date, sleeve gastrectomy is the most commonly performed bariatric procedure worldwide, it has demonstrated acceptable and durable weight loss as well as improve NAFLD and NASH.

Keywords: NAFLD, sleeve gastrectomy, liver steatosis

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is the most important cause of liver disease worldwide that is recognized as the liver component of metabolic syndrome [1, 2]. In addition, the experts suggested that NASH may soon become the most common indication for liver transplantation [3].

The estimated prevalence of non-alcoholic fatty liver disease worldwide is approximately 25% and is present in roughly 95% of patients who undergo bariatric surgery [4, 1].

* Corresponding Author's Email: ramiro.carbajal@gmail.com.

Moreover, the prevalence of NAFLD patients with type 2 diabetes is elevated with a prevalence rate estimated up to 70% [5]. Furthermore, the prevalence of NAFLD in patients who meet the criteria for metabolic syndrome rate has been estimated to be about 79% [6].

NAFLD includes a broad clinical spectrum ranging from nonalcoholic fatty liver to nonalcoholic steatohepatitis (NASH), advanced fibrosis, cirrhosis, and finally hepatocellular carcinoma (HCC) (table 1). It is important to emphasize that there is a strong association between NAFLD and obesity, insulin resistance or type 2 diabetes mellitus (T2DM) as well as dyslipidemia, suggests that NAFLD is the hepatic manifestation of the metabolic syndrome, also those patients have an increased mortality compared with the general population, with an increased risk of cardiovascular disease, hepatocellular carcinoma, and cirrhosis [7, 8].

Bariatric surgery achieves an improvement or even complete resolution of NAFLD in morbidly obese patients, these patients could be treated with laparoscopic sleeve gastrectomy preventing progression of NAFLD. The purpose of this chapter is to summarize the recent evidence about the effect of sleeve gastrectomy on liver steatosis.

NAFLD (NONALCOHOLIC FATTY LIVER DISEASE)

NAFLD is characterized by histological or radiographic evidence of fat accumulation in the liver (hepatic steatosis), with or without associated inflammation or fibrosis (steatohepatitis) after the exclusion of other causes of hepatic steatosis, including excessive alcohol consumption (< 20g in women and < 30g in men results in a low risk for the development of alcoholic liver injury) [9, 3].

Currently, Liver biopsy is the gold standard procedure utilizing the NAFLD activity score (NAS) for characterizing the severity of NAFLD and for diagnosing NASH (table 1) [10, 11].

Table 1. Spectrum of NAFLD

Disease	Subclassification	Most common concurrent disease
NAFLD*	NAFL	**AFLD-alcoholic fatty liver disease, Drug-induced fatty liver disease, Hepatitis C virus-associated fatty liver (genotype3), others, Haemochromatosis, coeliac disease, wilson´s disease, A/hypo-betalipoproteinemia lipoatrophy, hypopituitarism, hypothyroidism, starvation, parenteral nutrition, inborn errors of metabolism
	Pure steatosis	
	Steatosis and mild lobular inflammation	
	NASH	
	Early NASH: No or mild (F0-F1 fibrosis)	
	Fibrotic NASH: Significant ($\geq$ F2) or advanced ($\geq$ 3 bridging) fibrosis	
	NASH-Cirrhosis (F4)	
	Hepatocellular Carcinoma	

* Primary NAFLD: Associated with metabolic risk factors.

** Secondary NAFLD: May coexist with primary NAFLD.

AFLD: Alcoholic Fatty Liver Disease.

NAFL is characterized by steatosis of the liver, involving greater than 5% of parenchyma, with no evidence of hepatocyte injury [3].

NAFLD “is defined by the presence of steatosis in $> 5\%$ of hepatocytes according to histological analysis or by a proton density fat fraction (providing a rough estimation of the volume fraction of fatty material in the liver) $> 5.6\%$ assessed by proton magnetic resonance spectroscopy (HMRS) or quantitative fat/water selective magnetic resonance imaging (MRI)” [11].

“NASH is defined histologically by the presence of hepatic steatosis and two additional features: lobular inflammation and hepatocyte injury (ballooning)” [12] (Table 1).

NAFLD AND BARIATRIC SURGERY

Despite the increasing numbers of patients with NAFLD, therapeutic options are still limited. Weight loss is the main goal for patients with NAFLD because can lead to an improvement in liver biochemical tests, liver histology, serum insulin levels, and quality of life [13, 14]. In this context, Musso G et al. [15], reported that the 5% body weight reduction resulted in improvement in hepatic steatosis, whereas $> 7\%$ reduction was associated with NAS (NAFLD activity score) improvement.

There are several options to obtain weight loss, for instance, lifestyle modification, exercise, healthy diet. Moreover, weight loss is often problematic for patients to continue the needed lifestyle changes long term [16].

Bariatric surgery is the most effective long-term therapy for obesity and its complications and has shown to induce biochemical and histologic remission of NAFLD, through mechanisms of action that are both weight loss-dependent and weight loss-independent [17].

The exact mechanisms that lead to an improvement in NAFLD following bariatric surgery are not completely understood. Since Roux-en-Y gastric bypass (RYGB) is the second bariatric surgical procedure most performed worldwide, it is also the one from which the effects on NAFLD have been most studied, although there is also consistent evidence regarding the effects from gastric banding, sleeve gastrectomy and biliopancreatic diversions [18].

The association between NAFLD and type 2 diabetes mellitus (T2DM) has been well established, which could be explained by the insulin-resistance [17-20].

It comes as no surprise that mechanisms by which bariatric surgery improved the features of NAFLD would be related to weight loss, improvements in T2DM, reduced insulin resistance, reduced hyperlipidemia, and improved components of metabolic syndrome [21, 22].

Other proposed mechanisms would include the altered route of food delivery, which results in changes to the release of the gut and pancreatic hormones, changes in fat distribution, hepatic insulin and free fatty acid metabolism, and changes in adipocytokines and other cytokines [21]. Alterations in hormone secretion affect carbohydrate and lipid metabolism and interfere with hepatic glucose release [21]. In the last few years, recent studies have shown that changes in some gene expression and gut microbiota may also play a pivotal role [23-25].

Yung Lee et al. [26] performed a systematic review and meta-analysis, found that bariatric surgery leads to complete resolution of NAFLD in obese patients. However, some

patients develop new or worsened features of NAFLD, Perhaps, the primary limitation of this study is the heterogeneity between included studies.

Roux-en-Y gastric bypass (RYGB) is the most studied bariatric procedure for its effects on NAFLD, a 2019 systematic review found RYGB to have the greatest impact on NAFLD histology among all bariatric procedures and even suggests that bariatric surgery should be considered as a treatment of NAFLD [27, 28].

Effects of RYGB is discussed in detail in another chapter, in this chapter we will discuss the role of sleeve gastrectomy on NAFLD. At the time of writing this chapter the optimal bariatric procedure for patients with obesity and concomitant NAFLD remains to be defined.

SLEEVE GASTRECTOMY AND LIVER STEATOSIS

Currently, laparoscopic sleeve gastrectomy (LSG) is the most common performed bariatric procedure worldwide. LSG is considered to be safe and effective bariatric surgery with durable weight loss. In a recent study, was found that there were no statistically significant differences between sleeve gastrectomy and gastric bypass for weight loss or even to comorbidities such as of type 2 diabetes remission, dyslipidemia resolution, quality of live improvement, and late morbidity.

On the other hand, compared with sleeve gastrectomy, gastric bypass resulted in better resolution of hypertension, based on antihypertensive medication use [29].

Regarding advantages of LSG are low rate of complications, the short operative time, the absence of foreign material, the lack of gastrointestinal anastomosis and malabsorption, there is no mesenteric defects created eliminating the risk of internal hernia and has feasibility to be converted into multiple other bariatric procedures, but there are some issues to be considered such as weight regain, gastroesophageal reflux disease and Barrett's esophagus [30, 31].

Several publications have shown the improvement of NAFLD after bariatric procedures as RYGB as well as adjustable gastric banding (AGB), biliopancreatic diversion (BPD). However, little is known regarding this topic after LSG.

In a recent study Alsina ME, Ruiz-Tovar J and Bernabeu A [32], found that six months after sleeve gastrectomy, a significant reduction of liver steatosis is observed, as demonstrated by reduction in the percentage of intrahepatocitary lipids and liver volume, determined by MRS (Magnetic Resonance Spectroscopy) and MRI (Magnetic Resonance Imaging). In another study Esquivel et al. [33] it was found that sleeve gastrectomy significantly improves NAFLD after 12 months of follow-up, showing even a total regression in some of the patients without cases of worsening of the disease.

Outcomes on prospective data from 236 Patients, Karcz et al. [34] observed significant improvements in AST, ALT, triglycerides and high-density lipoprotein (HDL) levels one and three years after SG. NASH patients showed significant losses of body weight and amelioration of NASH status.

Algooneh et al. [35] did a retrospective study of 84 patients diagnosed with NAFLD prior to undergoing SG.

The diagnosis of NAFLD was achieved based on ultrasonographic imaging. A total of 47 patients (56%) showed complete resolution of NAFLD postoperatively.

Witigo von Schonfels et al. [36] performed a retrospective comparison of metabolic data before and after bariatric surgery and comparison of sleeve gastrectomy and Roux-Y gastric bypass, found that both surgery methods improved the NAS significantly, there was not differences with regard to histological recovery between gastric bypass and Sleeve Gastrectomy.

As has been noted the weight loss and improvements in obesity-related comorbidities, such as Type 2 Diabetes, insulin resistance, and hypertriglyceridemia, after sleeve gastrectomy plays a significant role in the improvement of NAFLD.

On the other hand, sleeve gastrectomy has been shown to result in increased FGF-19, decreased FGF-21, increased adiponectin, and decreased leptin, amylin, and ghrelin levels; no effect was seen on circulating bile acids, these aspects could improve the metabolic syndrome and thus may help improve NALFD [37].

FINAL CONSIDERATIONS

Until now, there is no established therapy and there are no evidence-based clinical guidelines about the treatment of NAFLD.

Sleeve gastrectomy could be a therapeutic option for appropriate, morbidly obese patients with NALFD and NASH, but more studies are needed to determine the long-term effects. Regarding this point, there have not been any adequate prospective, double-blind, controlled trials to provide the data necessary.

ABSTRACT

Given the known beneficial consequence of weight loss on NASH and the predictable effect of bariatric surgery on weight loss, several studies have explored the potential role of bariatric surgery on the treatment of NASH. To date, RYGB remains the most extensively studied bariatric surgery as a potential NASH therapy.

In this chapter we will review the actual evidence of the effect of RYGB on liver steatosis, NAFLD and NASH.

Keywords: steatosis, obesity, Roux-en-Y gastric bypass, NASH, fatty liver

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is an important cause of chronic liver failure in individuals without significant alcohol consumption [1]. It is the hepatic component of metabolic syndrome and is associated with the deposition of triglycerides into the hepatocytes. NAFLD includes a spectrum of syndromes ranging from pure steatosis (PS) to nonalcoholic steatohepatitis (NASH) to cirrhosis, which can lead to end-stage liver failure or development of hepatocellular carcinoma. While NASH is a condition with a high potential to progress to cirrhosis, PS appears to follow a more benign course, with little or no progression to further liver damage.

* Corresponding Author's Email: deluca.churruca@gmail.com.

As a result of the increasing prevalence of obesity, diabetes and metabolic syndrome, nonalcoholic fat liver disease (NAFLD) has become one of the most common cause of chronic liver disease worldwide [2]. In 2016, 39% of adults were overweight and 16%, obese [3]. In Argentina 60% of the population is overweight, and 5% is obese [4].

Differentiating patients with fibrosis, moderate fibrosis and severe fibrosis can be tricky. For NAFLD patients, the Original European Liver Fibrosis test has been proposed. It includes variables such as age, tissue inhibitor of matrix metalloproteinase 1, hyaluronic acid and aminoterminal peptide of pro-collagen II. A similar scoring system, the Enhanced Liver Fibrosis panel, excludes age and is also reliable [8]. The limitation for the routine use of these scores is the cost and *availability of the specific markers*. Diagnosis of advanced fibrosis is, indeed, an additional indication for bariatric surgery. However, the surgical procedure must induce a slow and progressive weight loss. More aggressive bariatric surgeries leading to more dramatic weight loss and malnutrition may worsen underlying liver disease [5]. Patients with fibrosis have a higher risk for cirrhosis, portal hypertension, hepatocarcinoma and death [6, 7].

RISK FACTORS

Insulin Resistance

It is considered a fundamental step in the development of the metabolic syndrome (MS), which can eventually end type 2 diabetes mellitus (T2DM). Both NAFLD and NASH are strongly linked to insulin resistance, and the relationship between MS and NAFLD is fully recognized. Insulin resistance facilitates the accumulation of fat in both abdominal subcutaneous adipose tissue and visceral abdominal adipose tissue, as well as in the liver.

Gender

NAFLD is more common in man than in women (ratio 2,1), apparently explained by the protective effect of estrogen, which also facilitate insulin function. As estrogen protects, androgens exert a potential *negative role in aggressive NASH*.

Ethnicity

The risk related to ethnicity has been researched in large multiethnic populations. It is considered that the prevalence of nonalcoholic fatty liver is higher in the *population of hispanic origin*.

Feeding

In obese patients with NAFLD, fat accumulates in the liver abnormally in the form of triglycerides, which are derived from lipolysis of adipose tissue by 60%, de novo lipogenesis by 26%, and by diet in the form of chylomicrons in 15%. In this abnormal deposit, the dietary imbalance between omega-6 and omega-3 fatty acids appears to be a determining factor. Fructose, which is increasingly consumed as an additive in commercial beverages, can alter lipidic metabolism. There is evidence that high fructose consumption triggers an increase in de novo lipogenesis, dyslipidemia, insulin resistance and obesity with central fat deposition. This de novo stimulus to lipogenesis contributes to increased deposits of fat in the pathogenesis of NAFLD.

PATHOGENESIS

NASH is a metabolic disease probably caused by multifaceted disturbances of hepatic lipid homeostasis. The pathogenesis of NAFLD is not fully understood. The theory of the two hits is the most accepted up to date. The first hit is the accumulation of fat in the liver, which takes to oxidative stress. The second hit is the development of inflammation (steatohepatitis).

As a result of insulin resistance vacuols of triglycerides are accumulated by the hepatocyte, leading to fatty liver.

Not all the fatty acids that are inside the liver have an exogenous origin because there is also a synthesis of fatty acids from the acetate. These fatty acids undergo transformations that will lead to different substances: Triglycerides Cholesterol Phospholipids Ketone bodies (after mitochondrial oxidation of fatty acids). Triglycerides bind to apoproteins and form lipoproteins, which is how they leave the liver to the blood. When they increase the fatty acids they accumulate in the form of triglycerides.

Mitochondria are essential for fat metabolism and can be a major source of oxidative stress under conditions of sepsis or lipotoxicity that is associated with *mitochondrial dysfunction*.

The fatty accumulation causes changes in hepatocyte's mitochondria leading to the production free radicals, oxidative stress and finally an inflammatory response with risk of fibrogenesis.

Free fatty acids can induce some microsomal lipogenases of cytochromes p-450 with the consequent production of free radicals, which are hepatotoxic, and lead to the induction of inflammation. The inflammatory process occurs in zone 3 or perisinusoidal. Chronic inflammation stimulates the activation of the strained or ITO cells and progenitors cells of the liver that lead to a reaction at the level of the bile duct with subsequent fibrosis and progression to cirrhosis. This occurs because the stellate or ITO cells, during chronic inflammatory process, lose their ability to store lipids and differentiate into cells with the characteristics of myofibroblasts, which synthesize type 1 and type 3 collagen in the perisinusoidal space with the consequently liver fibrosis development.

DIAGNOSIS

Diagnosis can be performed according to clinical and imaging criteria. However liver biopsy is the gold standard to assess steatosis, inflammatory activity and fibrosis; and make a differential diagnosis with other liver diseases. Biopsy is necessary but it has its limitations and is not risk-free. Timing is still controversial. Progressively, new studies have been developed and incorporated to investigate the degree of steatosis, inflammation and fibrosis. However standard guidelines are still lacking.

Most patients with NASH are asymptomatic, although some may suffer from fatigue, malaise, or right upper quadrant discomfort. Often the only clinical sign is hepatomegaly, which may not present in all patients. Few have cutaneous signs of chronic liver disease, but ascites, splenomegaly, spider angiomas, and palmar erythema suggest underlying cirrhosis with portal hypertension. However, some patients with NASH may have normal aminotransferase levels. Less than one half of individuals have a higher than normal alkaline phosphatase level, which is almost always modest, and a few have elevated serum conjugated bilirubin levels. The serum albumin and prothrombin time are typically normal *in the absence of cirrhosis*.

Regarding the lipid profile, the prevalence of metabolic syndrome and insulin resistance increase as the liver fat increases. The triglycerides values may be high, as well as VLDL and LDL and HDL values may be decreased.

Fibrosis is not required to histologically diagnose esteatosis liver, its usually macrovesicular that refers to hepatocytes with a single large intracytoplasmic fat drop displacing the *nucleus to the periphery cell*.

The extent of steatosis is assessed using percentage involvement by steatotic hepatocytes in liver parenchyma and reported as mild (5 - 33%), moderate (33 - 66%), and severe (> 66%). There are main histological scoring systems to grade and stage NASH. Grade refers to the amount of necro-inflammatory activity, which include the degree of steatosis, ballooning, and lobular inflammation. Stage refers to the categorization of the extent and location of fibrosis. The range of stages goes from 0 to 4.

Stage 0: no fibrosis

Stage 1: perisinusoidal/pericellular fibrosis

Stage 2: periportal fibrosis

Stage 3: bridging fibrosis

Stage 4: cirrhosis

Stage 4: cirrhosis

MEDICAL TREATMENT

To date, weight loss achieved via lifestyle intervention remains the mainstream treatment of NASH. A recent meta-analysis of 8 randomized controlled trials (RCTs) – 4 of which included post-treatment histology- involving 373 patients, showed that although $\geq 5\%$ total weight loss (TWL) improved hepatic steatosis, a $\geq 7\%$ TWL was required to improve NASH. [13].

Despite its benefits, in a recent trial by Vilar-Gomes et al. less than one third was able to achieve significant weight loss of $\geq 5\%$ and less than 10% was able to achieve weight loss of $\geq 10\%$ in this trial [14].

Other potential therapies to treat NASH include vitamin E, thiazolidinediones, glucagon-like peptide-1 (GLP-1) agonist, and obeticholic acid. Thus far, the best evidence is for vitamin E in nondiabetic adults with biopsy-proven NASH; and thiazolidinediones in patients with and without diabetes with biopsy-proven NASH.

Other therapies are currently undergoing research [15]. A low calorie diet (LCD) is recommended prior to the surgery. The optimal duration has not been determined but a preoperative 2-week LCD treatment seems sufficient for most patients in order to decrease liver volume and fat [16].

ROUX-EN-Y GASTRIC BYPASS AS A TREATMENT OF NASH

Given the known beneficial consequence of weight loss on NASH and the predictable effect of bariatric surgery on weight loss, several studies have explored the potential role of bariatric surgery on the treatment of NASH. To date, RYGB remains the most extensively studied bariatric surgery as a potential NASH therapy [17].

Typically, RYGBP involves the creation of a 30-50 mL pouch by stapling across the stomach, and then setting a Roux-en-Y gastrojejunostomy with a 15 mm stoma. The Roux limb is usually from 60 to 100 cm in length and the alimentary limb 100 to 200cm.

Figure 1. Standard RYGB technique.

Silverman et al. in 1995 evaluated liver histology in 91 patients before and at 2 to 61 months after RYGB. Out of 91 patients, 18 had no steatosis at baseline. Among the 73 remaining patients, 65 experienced reduction in steatosis in follow-up biopsies, 5 with minimal steatosis at baseline showed no change, and 3 had increased steatosis. Thirteen out of 91 patients had perisinusoidal fibrosis (PSF) at baseline—3 with bridging fibrosis, 1 with moderate fibrosis, and 9 with slight fibrosis. Following RYGB, PSF resolved in 10 patients, decreased in 1 patient and remained the same in 2 patients. One patient developed PSF after RYGB [18]. Mathurin et al. conducted a 5-year prospective cohort study on 381 patients with severe obesity. Liver biopsies were performed prior to and at 1 and 5 years after bariatric surgery. Gastric banding, biliopancreatic bypass, and RYGB were performed in 214 (56.2%), 87 (22.8%), and 80 (21%) patients, respectively. Compared to baseline, there was a significant improvement in the prevalence and severity of steatosis (frequency from 82 to 37.7%; extent from 37.4 to 16%) and a significant reduction in NAS (total NAS 1.9 to 1). Inflammation remained unchanged, while levels of fibrosis increased at 5 years (fibrosis stage 0.27 to 0.36). Despite this increase, 96% of patients had fibrosis score ≤ 1 suggesting that there was no clinically significant worsening in fibrosis. [19].

Lassailly et al. in 2015 conducted a 1-year prospective cohort study on 109 patients with biopsy-proven NASH and severe obesity. Liver biopsies were performed prior to and at 1 year after bariatric surgery.

Out of 109 patients, 70 (64.2%), 32 (29.4%), 6 (5.5%), and 1 (0.9%) underwent RYGB, gastric banding, sleeve gastrectomy, and biliopancreatic bypass, respectively. One year after surgery, 85% of patients had NASH remission. Compared to baseline, there was a significant reduction in the prevalence of steatosis from 60 to 10%. In contrast to the data from the previous study, fibrosis improved in 34% of the cohort at 1 year after RYGB [20].

A follow-up meta-analysis in 2015 assessed the effect of bariatric surgery on NAFLD liver histology and/or liver biochemistry. The analysis pooled 29 studies and demonstrated a significant reduction in the incidence of all NAFLD histologic features following bariatric surgery: steatosis (16 studies: reduction in the incidence by 50.2%), ballooning (8 studies: 67.7%), lobular inflammation (7 studies: 50.7%), portal inflammation (4 studies: 13.1%), and fibrosis (12 studies: 11.9%) [21].

Histological changes in liver parenchyma can be seen following weight loss of as little as 3 – 5% improving the steatotic burden. Histologic improvement in NASH can be seen at 7% total body weight loss, and decreased fibrosis is seen with further weight loss.

Weight Loss Surgery's (WLS) benefits go beyond slimming down. They are thought to be due to changes in the entero-insulin axis, helping to realign several dysfunctional processes, including insulin resistance, glucose metabolism, and hyperlipidemia [12]. Following RYGB specifically, there are substantial alterations in incretin signaling as part of this process. Increased concentrations of glucagon-like peptide-1 (GLP-1), elevations of gastric inhibitory peptide (GIP), and changes in substances such as peptide YY and oxyntomodulin after RYGB alter enteric signaling pathways. These incretin effects are unique to RYGB and are not seen with non-surgical weight loss. The immediate metabolic effects of RYGB, evidenced by rapid improvements in postoperative hyperglycemia in patients with T2DM, may play a role in biochemical mechanisms by which NAFLD improves. Conversely, the weight loss from the AGB is uniquely due to restrictive effects, while weight loss through VSG comes about primarily through combined restrictive effects and appetite suppression

through a decrease in ghrelin. Therefore, improvement of weight-related comorbid conditions tends to be higher with RYGB than with these other commonly offered procedures.

A rare and infrequently event associated with Roux-en-Y gastric bypass is aggressive non- alcoholic steatohepatitis. It is associated with rapid weight loss and/or malnutrition. Roux-en-Y gastric bypass is considered a safe procedure if drastic weight loss is avoided in the postoperative course. The mechanism of liver injury in aggressive steatohepatitis is unknown, but rapid fat mobilization in obese patients may potentially cause oxidative stress to the liver. Further study is needed to determine if there is a genetic predisposition to this form of injury and if antioxidants may protect the liver during rapid weight loss or malnutrition [22].

CONCLUSION

Non-alcoholic fatty liver disease is a known metabolic syndrome's comorbidity. It may potentially lead to fibrosis and cirrhosis. Bariatric surgery may lead to improvement and remission. RYGBP is the most evidence-based treatment. However, special care must be taken on patients with *faster than average weight loss*.

ABSTRACT

The association between *Non Alcoholic Fatty Liver Disease* and obesity has been clearly established, with almost all the obese population suffering some degree of it. Nowadays one third of liver transplants secondary to liver failure are due to NAFLD progression and it is estimated that by 2030 it could become the main cause.

Weight loss can significantly improve NAFLD and bariatric surgery is the most effective long term treatment for obesity and metabolic syndrome.

One anastomosis gastric bypass (OAGB) is a powerful technique with results comparable or superior to more established techniques and it should be considered as part of the armamentarium for treating NAFLD.

Keywords: liver steatosis, non alcoholic fatty liver disease, one anastomosis gastric bypass, cirrhosis

INTRODUCTION

Obesity is a pandemia that co-occurs and interacts with undernutrition and climate change, this constitutes a synergy of epidemics that represent the most serious threat to human health and survival [1].

* Corresponding Author's Email: lantozzi@gmail.com.

A large proportion of the obese population suffers metabolic syndrome, type 2 diabetes (T2DM), cardiovascular disease, dyslipidemia and non-alcoholic fatty liver disease (NAFLD). Persistence of this last comorbidity can lead to cirrhosis or hepatocarcinoma.

When liver damage presents with steatosis, steatohepatitis, fibrosis or cirrhosis in patients without alcoholic history, it is considered NAFLD. It affects 10-24% of the general population, but it can rise to 100% when patients are morbidly obese. Besides body fat percentage, central adiposity, hyperinsulinemia and insulin resistance are good predictors of liver dysfunction development [2-8].

Most patients with NAFLD remain asymptomatic or have vague symptoms like fatigue or mild right upper quadrant pain. In stages 3 and 4 of fibrosis, chronic liver disease signs like palmar erythema, telangiectasis or gynecomastia can be found.

During the evaluation of any liver disease, it is important to have initial blood samples of function tests. Most routine biochemical studies have poor correlation with NAFLD. Common blood sample findings are mild to moderate ALT and/or AST elevation. AST/ALT index usually remains under 1 but it rises with fibrosis progression along with gamma-glutamyl transferase. In steatohepatitis, inflammation is present and altered hepatic enzymes are frequently found. Alkaline phosphatase has been found to have statistical association with presence of NAFLD on biopsy [9]. Albumin, prothrombin or bilirubin alteration can indicate liver dysfunction or cirrhosis. In a study with 308 bariatric patients, *highly sensitive C reactive protein* (HSCRP) was found to have utility as an independent predictor of NASH [10].

Ultrasonography has 77% sensitivity and 80% specificity for detecting cirrhosis. For liver steatosis sensitivity rounds 90% with 97% specificity, but it cannot differentiate simple steatosis from steatohepatitis. CT scan and MRI can quantify steatosis and liver volume precisely. Despite imaging studies can detect fatty liver existence, they cannot distinguish hepatic damage severity, this can only be done with liver biopsies, the most precise study for the evaluation of treatment results [11-18].

One third of patients with early stage NASH will progress to fibrosis within 5 to 10 years after the clinical diagnosis has been made when left untreated. Weight loss can produce NAFLD regression, but 90-95% of patients fail to maintain this normal weight with only dietary measures. Bariatric surgery is an important tool to treat obesity comorbidities like NAFLD, being the most commonly performed procedures worldwide Sleeve Gastrectomy (SG) and Roux n Y Gastric Bypass (RYGB). Despite there are concerns about the fast and massive weight loss on liver function, disabsorptive techniques like One Anastomosis Gastric Bypass (OAGB) have demonstrated excellent long-term results. With proper indication and management, this can be a promising treatment for the unstoppable NAFLD rise.

SURGERY AND NAFLD

NAFLD remission or improvement can be related to weight loss, anatomical re-routing, simultaneous remission of comorbidities or by combination of these factors.

There is an established association and coexistence between NAFLD and metabolic comorbidities like insulin resistance (IR), dyslipidemia and T2DM. NAFLD is more severe in diabetic patients and higher rates of fibrosis are found when compared with pre-diabetic or

non-diabetic patients [19]. Metabolic effects like improved glucose homeostasis and lipid metabolism and reduced inflammatory activity that would influence NAFLD are observed after bariatric surgery. These effects are due to glucose and lipids metabolism and cannot be entirely explained by weight loss, since they start almost immediately after surgery. Mechanisms of steatosis and ballooning are linked to IR and the long-term evolution may be predicted by early improvement in IR after surgery [20].

Bile acids (BA) act as metabolic modulators and endogenous mediators of energy expenditure and glycolipid metabolism. Enterohepatic circulation is markedly modified when a bilio-pancreatic limb (BPL) without the presence of food is created. The concentration of primary and secondary BA in the portal vein and liver are found significantly elevated due to early reabsorption of the BP limb rather than accelerated transport to the ileum. The length of BPL is of particular importance and affects BA serum rise and they could be responsible for the glycemic control after surgery [21].

Surgery was found to be cost effective, to increase life expectancy, and quality-adjusted survival in patients with all classes of obesity, regardless of fibrosis stage [22]. Many studies have demonstrated significant improvement in histology and beneficial effects on steatosis but, to date, there are no randomized controlled trials showing histological effects of bariatric surgery in NAFLD patients.

Non-invasive methods to evaluate NAFLD changes after surgery, like serologic measurement of metabolic parameters and radiologic tests, are used to generate scores of steatosis or fibrosis. *Fatty liver liver index*, *NAFLD liver fat score* (steatosis), *Fibrosis 4 score* and *NAFLD fibrosis score* (fibrosis) are widely validated. Some publications used this method to analyze results but this cannot diagnose NASH [23, 24]. There is still scant data on the durability of NASH remission after surgery proved with biopsy. This can be a major limitation to indicate or conclude which surgery has best results for each patient.

NASH patients are at the highest risk of liver disease progression and dysfunction. Identification of these patients with biopsy and validated histological scoring is important. Bariatric surgery has been found to reduce hepatic fibrosis and necroinflammatory processes, slowing down the process and development of cirrhosis with further complications or death. This natural history of fibrosis or liver failure progression needs to be considered when a cohort of patients is evaluated, because they are most likely to suffer complications or unfavorable progression after surgery.

If cirrhosis is recognized before surgery, patients should be carefully optimized and informed before proceeding to an operation. Even well compensated Child's A patients can safely have surgery. There is no consensus on which bariatric modality is best suited. Access to biliary system and a simpler scenario if a liver transplant is needed are main advantages [25-28].

RESULTS

Bariatric surgery is more effective than medical treatment to achieve sustained weight loss, control insulin resistance, treat T2DM and reduce cardiovascular events. Regarding NAFLD several cohort studies assess the effect of Biliopancreatic Diversion, OAGB, RYGB, Laparoscopic Adjustable Gastric Band (LAGB) or SG. Resolution or improvement of

steatosis is the usual findings but there are reports of fibrosis worsening or progression. Transient deterioration of the liver condition mainly occur within the initial postoperative period in which nutritional status and transaminases, cholesterol, albumin or transferrin concentrations can be impaired [29]. LAGB and SG are found less detrimental than techniques that involve disabsorption. Initial liver status has to be evaluated to make proper patient and technique selection.

Numerous studies have pointed out an improvement in steatosis after bariatric surgery after 5 years of follow-up. This long-term evolution can be predicted by early improvement in IR following the surgical procedure. Correlation with weight loss is not linear but Glass et al. described regression in fibrosis when at least 10% of body weight is lost [30]. Luo found 83.7% steatosis resolution and a 21.4% decrease in liver volume at 1 month in 49 patients studied, indistinct of SG or RYGB [31].

In the largest study of BS in NAFLD with more than 500 patients, the effects of RYGB and AGB were compared. Improvement and resolution of steatosis, inflammation and fibrosis were observed after one and five years and the authors did not describe any cases of worsening. Best effects on weight loss and liver histology were achieved in the RYGB patients with greater weight loss and better glucose and lipid metabolism [32].

Another study of 160 patients demonstrated resolution or improvement of steatosis and inflammation in most patients, but 3/37 developed de novo steatosis, 3/114 de novo steatohepatitis and 12/56 de novo fibrosis after surgery, however this result could be affected by the short postoperative period between surgery and biopsy [33].

A recent study found histological NASH in 115 out of 1,489 (7.7%) morbid obese patients. After 109 were submitted to RYGB, LAGB or SG, persistent NASH was more frequent in LAGB than gastric bypass patients (30.4% vs. 7.6%; $p = 0.015$). NASH resolution was diagnosed in 85% of RYGB patients [34].

NAFLD activity score (NAS) higher than 4 is highly predictive of NASH and lower than 3 is highly predictive of its absence [35]. Froylich et al. compared RYGB and SG, they found $NAS > 4$ in 15 patients at the time of surgery and postoperative resolution were achieved in 14. Fibrosis also showed a significant improvement, but 12% of patients in the RYGB arm had worsening fibrosis stage postoperatively [36]. Mathurin et al. using NAS score at 1 and 5 years in 381 bariatric patients found improvement in steatosis and ballooning mainly within the first year that persisted up to 5 years. A lack of significant improvement in inflammation and fibrosis stage worsening at 5 years after surgery was also seen. Refractory IR and insufficient weight loss predicted the persistence of steatosis and ballooning [20].

Some degree of clinical or subclinical hepatic injury within the first year of disabsorptive procedures that generate rapid weight loss has been described [37]. Although progression to cirrhosis or liver failure is rare, there are patients that even required liver transplantation after BPD or Scopinaro [38-40].

A transient elevation in transaminases 6 months after BPD was published in a study of 697 patients, these parameters normalized after 12 months [41]. Biopsies found significant reduction of steatosis and NASH grade as well, confirming low detrimental effects of BPD [42].

Baltasar in a study of 470 patients reported that 10 (2.12%) had hepatic dysfunction not related to viral hepatitis or biliary ductal disease after BPD [43]. Ten years later another publication from the same author reported 1.2% liver disfunction and 0.2% liver failure in a series of 929 patients with the same operation [44].

Giannini et al. investigated the safety of BPD in 56 compensated NAFLD patients at 5 years. Of the patients with baseline NAS score 0-2, it remained unchanged after surgery in 76% of the cases and 24% became indeterminate. Of baseline indeterminate NAS patients, 56% remained unchanged, 41% improved and 3% worsened. Among 8 patients with F3-F4 one remained unchanged, 2 improved to F0-F2 and 5 became indeterminate. None of the patients in this series developed liver related complications. They concluded that liver damage does not seem to be a contraindication to BPD [37].

Texeira reported a patient with BMI 69 kg/m² submitted to single anastomosis duodeno-ileal bypass (SADI). He consulted at the third year after poor follow-up compliance with 83% EWL, hypoalbuminemia, ascites and cirrhosis [45]. He was treated conservatively but later required revision to RYGB (unpublished).

In a large retrospective analysis of 2,241 patients, Scopinaro did not find any liver failure after his procedure was performed [46].

With jejunioileal bypass (JIB) pioneered by Payne and DeWind, an association between disabsorption and liver complications was found. The technique was abandoned because, among other aspects, the possibility of developing hepatic fibrosis was found in 45% of patients and cirrhosis in 8% [47]. In a review of 6,319 patients, mortality after JIB was 2.8%. Twenty one percent of the 179 fatal cases occurred within 1 month after surgery. Only 2.9% of patients showed progression of liver disease. In another review, 10 out of 604 patients (1.7%) died of liver failure [48].

Liver impairment mechanism after disabsorptive procedures remains unclear and some groups suggest to avoid this technique if advanced liver compromise is detected prior to surgery. On the other hand, there is a significant association between metabolic comorbidities remission and NAFLD improvement. Disabsorptive techniques are most efficient in this aspect and it is logical to think that best NAFLD remission would be found after they are performed. Only a few studies evaluated what happens with the metabolic effect of surgery when patients regain weight. With re-emergence of initially controlled T2DM and weight recidivism [49], lessening in the improvement of NAFLD outcomes [50] and liver enzymes rise has been demonstrated [51].

The latest guidelines discussing surgical treatment of NAFLD state that surgery is clearly indicated in patients with NAFLD who also meet the criteria for bariatric surgery, but with no specific statement regarding the choice of the procedure [52-53].

OAGB is among the most efficient bariatric techniques regarding long-term results, not only because of weight loss maintenance but also comorbidities resolution. Despite its relative novelty, this technique will find its place within the therapeutic armamentarium for treating NAFLD.

ONE ANASTOMOSIS GASTRIC BYPASS (OAGB)

In 1997, Dr. Robert Rutledge, during a trauma surgery that required antrectomy and intestinal resection, performed a reconstruction with a single gastro-jejunal anastomosis. This reconstruction led to the mini-gastric bypass (MGB) operation, later applied to treat obesity and related comorbidities being less technically demanding than RYGB. In 2001 Dr. Rutledge made the first presentation of excellent results after 1,274 patients. In 2002, Professor Miguel Carbajo, an experienced bariatric surgeon, performed a modification to avoid potential reflux

entitling the surgery as one-anastomosis gastric bypass (OAGB) or BAGUA in Spanish. [54] Some modifications have been described with time, trying to reach the operations *State-of-the-art*.

In April 2018 the *International Federation for the Surgery of Obesity and Metabolic Disorders* (IFSO) has determined that the standard nomenclature when referring to the mini gastric bypass described by Rutledge and the one anastomosis gastric bypass described by Carbajo should be One anastomosis gastric bypass (OAGB) [55]. Technical aspects are described below.

MGB consists of a long gastric pouch starting 2-3 cm. below the *Crow's foot* that extends to the angle of His. A 4-6 cm. wide termino-lateral gastro-jejunal anastomosis is constructed leaving a BPL of 150-200 cm. without measuring the total bowel length. In the super obese, the recommended distance to *Treitz* ligament is about 250 cm, in the elderly less than 150 cm. and in type II diabetics without major obesity about 150 cm. [56]

OAGB consists of an 18-20 cm. gastric pouch, an anti-reflux valve conformed by suturing the BPL to the gastric pouch and a latero-lateral gastro-intestinal anastomosis. The most significant difference between surgeries is total bowel length measurement. Bowel length has been found to be variable and this can be important enough to predispose a patient to malnutrition or others to weight regain when fix BPL length is used. Dr. Tacchino observed that 3% of women and 2% of men have small bowel shorter than 400 cm, and interestingly in opposition 15% of men and 5% of women have it longer than 800 cm. [57] Drs. Carbajo and Tovar found in a 5 years prospective observational study of 300 patients that the common limb/total bowel length ratio, followed by common limb length are the most accurate parameters to predict 5-year postoperative BMI below 25 Kg/m². An ideal range between 0.40 and 0.43 was established (unpublished). They found less variability in total bowel length than Tacchino, but again a group of patients with the risk of a common limb too short was detected if TBL is not measured.

This topic is of particular importance if a patient has liver disease, since the procedure can be tailored knowing the existence of this comorbidity. Longer common limb is safer in these cases. A disabsorption too powerful can lead to not only lack of regression of the disease, but progression or liver failure. Rapid weight loss can affect the liver function.

OAGB AND LIVER DISEASE

In a recent systematic meta-analysis, that included studies in English with more than 100 patients as selection criteria, 35 relevant publications about OAGB and 8 registered clinical trials were found. Of this literature review almost every group performed liver function tests and radiologic liver evaluation with US prior to surgical interventions, but results on this topic are barely described.

Eilenberg published a case series of 10 patients with liver dysfunction after RYGB, OAGB and Distal Gastric Bypass. Unfortunately the number of initial surgeries from which this group resulted in is unknown. Three patients had primary OAGB, 2 were converted OAGB after gastric band, 3 had primary RYGB and 2 had RYGB distalization. Clinical presentation was characterized by an increase in liver enzymes, hepato-splenomegaly, thrombocytopenia, impaired coagulation parameters, hypoalbuminemia, and sarcopenia. At

later stages, ascites, pleural effusions, encephalopathy and upper gastrointestinal bleeding. Seven developed steatosis/fibrosis and 3 cirrhosis. Eight patients were successfully treated with nutritional preparation and conversion. One OAGB patient required liver transplantation and one RYGB died of decompensated liver disease prior to conversion [58].

Kruschitz retrospective evaluation of 25 non-diabetic patients who underwent OAGB and 25 RYGB found a transient rise in ALT and AST. De Ritis ratio significantly greater in omega-loop gastric bypass after 12 months and faster reduction of GGT in RYGB were observed. Despite the small sample size and that liver biopsies were not available, this is one of few papers assessing important information on this subject [59].

Spivak published a database analysis of 19,053 patients submitted to SG, 2433 to RYGB and 715 to OAGB. EWL superiority was seen in OAGB. Awareness of liver markers on hepatic condition was raised and authors suggest close follow-up if markers at one year switch from normal to abnormal. The percentage of patients with normal baseline AST/ALT that became abnormal was 10%-11.7% in OAGB patients at the first year after the procedure; ALP levels became abnormal in 15.7%. The percentage of patients who went from abnormal to normal AST, ALT, and GGT was significantly higher and outnumbered that of normal to abnormal patients for all 3 procedures, although the differences were lower in OAGB patients [60].

Carbajo reported a 12 years follow-up retrospective study of a prospective database. Of 1200 consecutive patients T2DM, IR, HT, and sleep apnea either totally resolved or substantially improved within the initial period after OAGB. Remission was also demonstrated in most patients for other metabolic conditions like hyperlipidemia and liver steatosis when the first biochemical tests were ordered at the 3rd postoperative month. At 12 years mean EWL was 70%. Early major complications requiring re-operations occurred in 1.3 % (9 bleedings and 3 leaks). Two percent of the patients reported sporadic clinical reflux that was managed conservatively [61].

A study of 3000 patients submitted to OAGB showed, after 15 years, a slight to moderate decrease in the percentage of full remission in patients with T2DM (from 94% to 90%), hypertension (from 98% to 87%) and hyperlipidemia (from 98 to 86%) but sustained complete remission of fatty liver disease [62].

Drs. Kular and Rutledge reported their results in a retrospective review of prospective data on 1,054 consecutive patients. With a follow-up of 84% at 6 years they found 85% EWL, 93.2% diabetes and 99% fatty liver remission [63].

Garg et al. researched the utility of transient elastography to evaluate the effect of bariatric surgery on hepatic steatosis and fibrosis with liver stiffness measurement (LSM) and controlled attenuation parameter (CAP). Of 124 patients, 32 underwent biopsy at one year. They found no difference in changes of hepatic steatosis, lobular inflammation, ballooning, NASH and fibrosis between LSG, RYGB and OAGB. Biopsy results were comparable to LSM and CAP [64].

In December 2017 a total of 101 experts from 39 countries evaluated 55 topics during a consensus statement meeting. Seventy-six experts agreed that OAGB is an acceptable surgical option in suitable even in patients with Child-Pugh class A cirrhosis without portal hypertension (75.25% consent) [65].

OAGB RESULTS

It is now widely acknowledged that OAGB is an efficacious technique for achieving sustained weight loss [66-67]. Complete remission or improvement of T2DM is among the greatest found in BS [68-71] and comparable with more complex surgeries like BPD [72-74].

Lee evaluated T2DM remission at one year in 249 MGB and 157 RYGB patients. Complete remission was achieved in 55.4% of patients in RYGB group and in 81.9% of patients in MGB group at 1 year. At 5 year follow-up, results were still significantly better in MGB group (70.5% vs. 39.4%) [75]. The same author in a double-blind randomized trial that included 60 patients, showed MGB superiority over SG in patients with BMI 25-35 kg/m² up to 5 years after surgery. A statistically significant difference in HbA1C was reported (6.1 ± 0.7 vs. $7.1 \pm 1.2\%$, $p < 0.05$) [76]. Another prospective, randomized clinical trial by Lee compared 40 RYGB and 40 MGB at 2 years follow-up. There were no statistically significant differences in WL, quality of life or clinical results. The author concludes that MGB is a simpler technique than RYGB with similar efficacy [77].

Wang et al. in a systematic review and meta-analysis examined the results of OAGB and SG. EWL was greater after OAGB at one ($p = 0.005$) and five years ($p < 0.001$). Remission of diabetes was significantly better in OAGB ($p = 0.002$) [78]. Quan et al. revised 16 studies and showed superiority of MGB regarding EWL and T2DM remission over SG (89.1% vs. 76.3%, $p = 0.004$) and RYGB (93.4% vs. 77.6%, $p = 0.006$) [79].

Magoulitis et al. in a systematic review of 10 studies that included 6761 patients found that EWL, T2DM and dyslipidemia remission were significantly superior in OAGB than SG. Anyway authors mention that regarding this topic only a small number of RCT were found and results should be cautiously interpreted. The same group compared clinical outcomes of OAGB and RYGB one year later and again found superiority in EWL at five years and T2DM remission, but not dyslipidemia [80].

A recent prospective randomized clinical trial by Tovar compared 600 patients submitted to SG, RYGB and OAGB at 1, 2 and 5 years. Excess BMI lost at 1 year was 81.7 ± 6.3 in SG, 81.2 ± 5.9 in RYGB and $100.4 \pm 6.7\%$ in OAGB. At 2 years 87 ± 7.1 in SG, 87.2 ± 6.7 in RYGB and $104.3 \pm 7\%$ in OAGB. Both measurements showed significantly better result of OAGB, and no statistically significant different between SG and RYGB. Five years after surgery the same results were found. Final results were in SG group BMI 30.8 ± 2.2 , in RYGB 29.9 ± 2.3 and OAGB 25.1 ± 1.8 ($p < 0.001$). Five year remission of diabetes was 82% for SG, 86.4% for RYGB and 95.7% in OAGB. ($p = 0.027$). Five year remission of DL was 28.6% for SG, 71% for RYGB and 100% in OAGB. ($p = 0.001$) [81].

Alkhalifah in a retrospective analysis of a prospective database compared 1731 MGB, 805 RYGB and 1107 SG. Maximum weight loss was achieved in all patients at 2 years. MGB showed significant and durable WL at 10 years. At 2 and 5 years MGB group had the highest remission rates of T2DM (95.1%) and dyslipidemia (87.7%). SG had similar efficacy in diabetes remission rate to both bypass procedures, but significantly lower values in the treatment of dyslipidemia [82].

Jammu and Sharma compared SG, RYGB and MGB in 1107 patients with 52% follow up at 7 years. In the long-term excess weight loss was >90% after MGB, 72% after RYGB and 53% after SG. T2DM remission was 56.5% in SG, 75.8% in RYGB and 95.1% in MGB. DLP remission was 52.4% in SG, 74.0% in RYGB and 93.3% in MGB. Hypoalbuminemia was

maximum in MGB. The authors concluded from the results found that MGB was the procedure of choice for patients compliant in taking supplementation [83].

A RCT comparing efficacy of RYGB and OAGB found 60% complete remission of T2DM in OAGB compared with 38% in RYGB [84].

COMPLICATIONS AFTER OAGB

Complications after OAGB are being continuously studied and mostly reported as infrequent. Mortality and early complications rate have been found comparable to SG and RYGB, but with a favorable trend in late complications rate and re-intervention needs. Publications repeatedly mention the possibility of conservative management before the necessity of a surgical intervention. Bile reflux (0.2-2%) and PCM (0.2-1.2%) are main concerns and primary hepatic related complications are not common [85-87].

Revisional surgery is the third most commonly performed bariatric procedure nowadays because of poor primary surgery outcomes. SG can't be reversed, and revision hasn't shown good results, but it is frequently converted. Indications for SG conversion are weight regain, comorbidities persistence and/or GERD. Usually these patients can have a RYGB, BPD or OAGB. After RYGB failure, it is difficult to find a simple and effective solution. Pouch and/or anastomosis reshaping and limb distalization are complex and not very successful. Transformation to OAGB with BPL distalization can achieve comorbidities resolution and weight loss.

OAGB can be revised, converted or reversed with less technical difficulties than RYGB. The main indications are protein calorie malnutrition (PCM), and intractable reflux. These conditions mostly appear within the first 18 months after surgery and should be properly managed clinically before indicating surgery, since most cases respond. Weight regain can also appear in the medium or long-term after MGB.

PCM is associated with poor alimentary habits or to a common limb too short. The incidence is more frequent in vegetarians, diabetic nephropathy, and liver disease patients. Patients can present with lower limbs edema, fatigue and severe hypoalbuminemia.

A systematic review of 12,807 OAGB patients found low postoperative hypoalbuminemia rates (3.4%) and reported occurrence of PCM in 0-3.8% of patients at 2 years [88].

Khalaj et al. in a study of 189 patients submitted to MGB with 200 cm. BPL had the highest published readmission rate secondary to PCM (7/189, 3.7%). Liver function tests were normal in all patients before surgery and 5/7 had different grades of steatosis in US. High serum transaminases was found in only one patient at a mean period of 11.7 +/- 4.5 months but rose in 6/7 during follow-up visits. All patients underwent revisional surgery. Of the seven cases, a patient that expired had a history at baseline of DMTII, HT, grade III fatty liver and failed to progress after gastro-gastrostomy. Common limb length in autopsy was 108 cm [89].

Alkhalifah compared SG, RYGB and MGB. Seventy out of 1,731 MGB patients required revision (4%). Malnutrition was the main cause (43 cases) followed by intolerance, and WR. In RYGB revision rate was higher reaching 5.1% with 41.5% secondary to acute internal

herniation, 24.4% for WR and 14.6% for malnutrition. SG revision was highest at 5.2% with 89.6% of the cases secondary to GERD or WR [82].

Jammu and Sharma during their initial experience with a longer BPL >250 cm. had 13.1% of patients with hypoalbuminemia and 3.2% of the cases had to be reversed. This observation changed their approach on limb length supporting a shorter BPL [83].

Motamedi reported a morbidly obese patient who underwent MGB that progressed from a baseline NAS 2/8 to 7/8 nine months after surgery. The case was resolved after gastro-gastrostomy [91].

Finally Robert in a multi-centre, non-inferiority, randomized controlled trial found OAGB to be not inferior to RYGB in terms of weight loss and metabolic outcomes at 2 years. Single adverse events can be interpreted as higher throughout the paper but a detailed reading by Mahawar pointed out that actually there was no significant difference in the proportion of patients with at least one serious adverse event (22% with OAGB vs 19% with RYGB; $p = 0.19$). Early and late complications combined was the same for both procedures [92]. The incidence of malnutrition at 2 years was also not significantly different between the groups (OAGB 10.8% vs RYGB 16.7%; $p = 0.34$) [84].

CONCLUSION

Bariatric surgery improves NAFLD in patients with obesity. Despite there are reports of increased de novo fibrosis, development of cirrhosis or liver function alterations are infrequent with modern surgical techniques. Natural progression of NAFLD in the common metabolic syndrome - obesity scenario, makes the decision of performing surgery quite easy. Which technique to choose is far more complex and depends on patients condition, possibility of follow-up, dietary habits and medical team experience or preferences.

There are not many publications specifically addressing liver impact of OAGB but this chapter summarizes that weight loss and comorbidities resolution are of importance for NAFLD control. OAGB is becoming a mainstream because it is proving to be superior to other procedures in these aspects.

Groups starting to adopt this technique should be properly trained and compromised with follow-up and monitoring of liver function tests. If a proper technique and supplementation/diet are utilized, results are optimal and risks minimized.

Department of Surgery, Hospital Clinico San Carlos, Madrid, Spain

ABSTRACT

SADI-S is a new bariatric procedure that basically consists of a sleeve gastrectomy with a one-anastomosis biliopancreatic diversion. SADI-S has been developed to simplify biliopancreatic diversion without modifying its effectiveness.

Long-term results of SADI-S are lacking but the early and medium-term results are encouraging. Natural history of Non-alcoholic fatty liver disease after SADIS has not been previously studied. However, due to the good results on metabolic comorbidities remission after SADIS, we believe that SADI-S will probably provoke a high percentage of remission in Non-alcoholic fatty liver disease.

Herein, we present a study about the relationship between obesity in bariatric surgery patients and genes that are related to hepatocellular carcinoma. In the future, we will study the change on these genes after SADI-S.

Keywords: bariatric surgery, morbid obesity, non-alcoholic fatty liver disease, non-alcoholic steatohepatitis, Single Anastomosis Duodeno Ileal Bypass with Sleeve Gastrectomy, SADIS

INTRODUCTION

SADI-S is one of the most recent innovations in bariatric surgery. It represents the continuous research and evolution in this field to find more effective and safer solutions when treating the obesity epidemic and metabolic related diseases. As already occurred with the mini-gastric bypass or one anastomosis gastric bypass, single anastomosis duodenoileal bypass with sleeve gastrectomy is basically a one anastomosis biliopancreatic diversion (BPD)-duodenal switch (DS) procedure and represents another alternative in the armamentarium of the bariatric surgeon. As often occurs with novel procedures, the nomenclature is not yet standardized: it is defined according to different authors as single anastomosis ileal bypass, loop duodenal switch, mini-DS, duodenoenteral omega switch, stomach intestinal pylorus-sparing (SIPS) surgery. With some differences in gastric tube size and intestinal bypass length, the principle is the same: it is less demanding and eliminates the Roux limb and can potentially reduce postoperative complications without losing metabolic effectiveness of the BPD-DS [1, 2].

Malabsorptive bariatric techniques were initially derived from the metabolic outcomes of massive intestinal resection (usually following mesenteric infarction). The first bariatric procedures were the jejuno-ileal bypass and jejuno-colic bypass, techniques which gave good weight loss and improvement/remission of the metabolic conditions accompanying obesity.

Unfortunately, these procedures were associated with severe late nutritional complications that caused them to be abandoned [1, 2]. In an attempt to deal with these nutritional complications, Nicola Scopinaro developed the biliopancreatic diversion with the intention of maintaining malabsorption while avoiding major uncontrolled malabsorption, disruption of the enterohepatic cycle, and the presence of a long blind loop. One of the features of Scopinaro's technique was the concept of "the three limbs": the alimentary limb, biliopancreatic limb and the common channel. Over the years, several different groups have demonstrated different results based on the varying length of these limbs. The Scopinaro procedure was modified in 1988 by Hess et al. into the BPD-DS. It offered two advantages over previous operations: a vertical gastrectomy along the greater curvature to preserve the integrity of the antropyloric region, as well as a modification of the length of the common channel to 100 cm [2].

The major obstacles of BPD-DS are its technical complexity, complication rates, and possibility of long-term nutritional issues. Nevertheless, BPD and BPD-DS are considered among the best options for selected morbidly obese patients with associated diseases.

To simplify such an effective procedure and preserve its principles, the single anastomosis duodenoileal bypass with sleeve gastrectomy (SADI-S) was first described in 2007 by Sánchez-Pernaute and Torres [3]. SADI-S compared with DS eliminates the Roux-en-Y gastric bypass by creating an omega loop, and because of pylorus preservation, bile diversion is unnecessary as the natural barrier remains in place. Preservation of the pylorus provides control of solid stool emptying, reducing the chances of dumping syndrome and assisting in the maintenance of a physiologically based rate of gastric emptying. The immediate benefit is the need for only one anastomosis, thus saving operative time and potentially reducing postoperative complications. Moreover, since it does not require a mesenteric opening, there is a reduced risk of internal hernia. SADI-S is a solution to determining a decrease in the postoperative and nutritional effects of BPD-DS while

maintaining weight and metabolic benefits linked to fundus resection, pylorus preservation, duodenal exclusion, ileal brake effect, and fat malabsorption [2].

It also represents a valid option for revisional surgery after failed sleeve gastrectomy (SG). With SADI, the malabsorptive component is added to an essentially restrictive procedure, as the DS is the natural complement to SG for improving weight loss outcomes and sustainability. Furthermore, it is easier for the surgeon to perform a oneloop duodeno-ileal bypass in “virgin territory.” Furthermore, when there is evidence of dilation of the sleeve construction, SADI may also be performed with a concomitant resleeve gastrectomy [2].

Moreover, SADI-S is a versatile procedure. According to patient characteristics and surgeon preference, it can be performed with a narrow gastric pouch and a long common channel (300 or 350 cm) or simply remain a malabsorptive procedure with a short common channel (200 or 250 cm) and a wider gastric pouch. Initially, Sanchez-Pernaute technique consisted a wide sleeve gastrectomy (54 French intragastric bougie) and a one-loop duodenal switch with a 200 cm common channel. This was based on analysis of outcomes of BPD variants. The SADI-S with a 200 cm efferent limb, carried an 8% incidence of clinical malnutrition, and 4% of our patients had to be re-operated to lengthen the common channel. Although these lengthening procedures were considered to be secondary to poor dietary compliance, after this experience they chose to perform a safer procedure by enlarging the common channel to 250 cm.

Standardization of nomenclature and technique, together with further studies with long-term outcomes, are needed to confirm the safety and efficacy of SADI-S in the routine surgical management of the obese population.

RESULTS OF SADI-S. WHAT WE KNOW SO FAR

Since SADI-S is a novel technique in bariatric surgery, having been first described by Sanchez-Pernaute et al. in 2007, there is still some lack of long-term results. However, the literature published about this topic reinforces the idea that SADI-S is a safe and effective technique with a similar efficacy to BPD-DS in weight loss and control of comorbidities such as hypertension, sleep apnea and type 2 diabetes mellitus. While some of the induced physiologic mechanisms of both techniques are overlapping, it is thought that others are different and still not well understood.

The prevalence of Non-Alcoholic Fatty Liver Disease (NAFLD) is rising and is estimated to have doubled in the last 20 years, with rates between 2-44% in the European population and 42,6-69,5% in patients with type 2 diabetes mellitus. Reports suggest that 87-94% of bariatric patients demonstrate abnormal non-alcoholic liver pathology [4]. We know that bariatric surgery is associated with a significant reduction in the incidence of a number of histological features of NAFLD as steatosis, fibrosis, hepatocyte ballooning and lobular inflammation. Also, surgery is associated with reduction in liver enzyme levels (ALT, AST, ALP and gamma-GT) [4, 5].

The group of Sanchez-Pernaute pioneered this technique and published some interesting results [6]. For example, for diabetic obese patients they found remission of T2 DM in 84% of operated patients. They have also observed a significative effect of the lypidic profile, with 89% normalizing tryglicerides, 65% HDL, 79% LDL and 96% normal total cholesterol.

Hypertension remitted in 52% and improved in 44%. Also, hypoalbuminemia was detected in 12%, low vitamin A levels in 53% and high PTH levels in 54%. Moreover, this group has observed that in the mid-term SADI-S is at least as effective as other malabsorptive techniques such as BPD/DS and significantly reduces the four main cardiovascular risk factors to a higher extent than RYGB [7].

Zaveri et al. published in 2018 their mid-term outcomes at 4 years [8]. For 437 patients operated, they observed a complication rate of 7,7%. The T2 DM remission rate was 97,6%, and the EWL% was 85,7+/-27,3%.

Shoar et al. published the most complete systematic review about efficacy and safety in 2017 [9]. It comprehended 12 studies including 581 SADI-S patients, being a primary procedure in 87,4% and a conversion procedure in 12,6%. The EWL% average was 85% at 2 years of follow-up. About co-morbidities, a remission rate was observed in 74,1% for T2 DM; 96,3% for HTN; 68,3% for dyslipemia; 63,3% for sleep apnea and 87,5% for GERD. Proteic malnutrition was observed in 34% of patients.

Moreover, some studies have been published in recent years comparing the results of SADI-S with other techniques of bariatric surgery.

Moon et al. published a retrospective study in 2015 comparing the safety and effectiveness of the single versus double anastomosis duodenal switch [10]. They studied 111 SADI-S and 74 DS, obtaining comparable results in terms of weight loss (44,2% vs 48,4% at 24 months). They also recommended a close nutritional follow-up for both techniques, finding hypovitaminosis D in 40% to 60% of the patients studied.

Other groups as Sessa et al., have compared the effects of glucose tolerance testing between SADI-S and other bariatric procedures [11]. They published in 2019 their conclusions. Not surprisingly, BPD and SADI-S seems to be associated to an improvement of insulin sensitivity and glucose homeostasis. Also, a reduced risk of hyperinsulinemia and hypoglycemia was observed, associated with RYGBP and SG.

Also in 2019, Wang et al. published an interesting study using a mildly obese and diabetic rat model to compare diabetes remission and micronutrient deficiency between SADI-S and RYGBP. They divided 30 rats in three equal groups, performing sham operation, SADI-S and RYGB [12]. The two latter groups achieved almost the same efficacy in caloric restriction and fasting plasma glucose control without excessive weight loss. They also showed comparable effects on insulin sensitivity and β cell function. It was remarkable that only RYGB showed changes in gut hormones and vitamin E deficit. These results suggest that diabetes improvement is reached through overlapping and distinct mechanisms in each technique.

About the different mechanisms of action depending on the surgical techniques, Pereira et al. published a study in 2018 where they compared post-prandial hormone profiles between BPD-DS and SADI-S [13]. Two groups of 9 patients each with no past or current diabetes underwent a liquid mixed-meal tolerance test. It was observed that after SADI-S the post-prandial hormone secretion profile presented increased GLP-1, glucagon and insulin secretion when compared to BPD-DS. The authors think that the higher levels of GLP-1 after SADI-S could be attributed to bile acids interactions across a longer intestinal length (300 cm) than in BPD-DS (100 cm). This could also explain in part the higher insulin secretion. About the glucagon secretion, the mechanisms remain unclear, but it could also be triggered by bile acids stimulation. It is apparent that there are some mechanisms that need further investigation to understand these results.

Finally, it is important to note that even when it is reasonable to expect good results in the evolution of NAFLD/NASH after SADI-S, it has also been described by Kirkpatrick et al. at least one case with liver cirrhosis following SADI-S [14]. It is thought that this could be secondary to bacterial overgrowth, protein malnutrition and mobilization of free fatty acids from adipose tissue that could exceed the capacity of the hepatocytes to metabolize and cause steatosis and oxidative damage. All these mechanisms are not unique after SADI-S and it is important to keep in mind this possibility after surgery.

ANALYSIS OF LIVER GENETIC ALTERATIONS IN PATIENTS SUBMITTED TO SADI-S

NAFLD has been related to hepatocellular carcinoma (HCC) [15]. As a first step to understand how NAFLD can promote HCC and how bariatric surgery and SADI-S can avoid HCC provoked by NAFLD, we have studied the liver genetic alterations in a cohort of patients submitted to SADI-S [16]. In the future, our aim is to analyze if bariatric surgery is able to reverse these genetic alterations.

MATERIAL AND METHODS

Twenty-six patients who underwent surgery in the Department of Surgery of Hospital Clínico San Carlos in Madrid (Spain) were included in the study. Seven patients were control patients not submitted to bariatric surgery and 19 patients had morbid obesity and underwent SADI-S as a bariatric surgery procedure. All patients signed an informed consent before being included in the study.

A liver sample was collected during the surgery in all the patients. Patients were classified according to the histologic severity of NAFLD as normal liver, mild/moderate steatosis, severe steatosis and non-alcoholic steatohepatitis (NASH). All the controls had a normal liver sample, mild/moderate steatosis was diagnosed in 14 patients, severe steatosis in 3 patients and NASH in 2. Due to the low number of patients in the severe steatosis and NASH groups, these patients were excluded and control patients were compared to patients with mild/moderate steatosis.

Liver samples were stored at -80°C. RNA was isolated by spraying 25-30 mg of the sample with NucleoSpin RNA/Protein system (Macherey-Nagel, Oensingen, Switzerland). Complementary DNA (cDNA) was synthesized using 1 µg of RNA. First it was mixed during 5 minutes at 65°C with primer poli dT (Roche, Basel, Switzerland) and dNTP (Invitrogen, Carlsbad, California, USA). Then it was mixed during one hour at 50°C with reverse transcriptase Superscript III RNase H Reverse Transcriptase (Invitrogen, Carlsbad, California, USA), DTT and RNA inhibitor RNAsin (Promega, Madrid, Spain). Finally, to get the quantitative PCR (RT-gPCR) the 799HT Perkin-Elmer Applied Biosystems system was used with Fast Start DNA Master SYBR Green I Kit (Roche, Basel, Switzerland).

To decide which genes would be studied, a pool analysis was performed at the beginning of the study. cDNA of different patients in the same histologic group was mixed. These cDNA were analyzed for 70 genes. Sixteen genes were chosen because the genetic expression

was different in the pooled cDNA from controls and patients with NAFLD. Other 32 genes were chosen after reviewing the published information about this issue. Some of the genes that were finally studied were TGF-B, BMP, IGF2, IGF1, IRS, IR receptor, TGF-A, HGF, Met, IL6, TNF, NADPH. NOX2. Alox5, MMP7, MMP9 and alpha-fetoprotein.

Quantitative variables are expressed as mean (QR). Genetic expression in the control and mild/moderate steatosis was compared using Mann-Whitney U test. Results with a $p < 0.05$ were considered statistically significant.

RESULTS

Table 1. Compares the characteristics of patients in the control and mild/moderate steatosis group

	Control	Mild/moderate steatosis	P
Age (years)	44 (32-55)	51 (41-56)	$p > 0.05$
Gender (% female patients)	71%	53%	$p > 0.05$
Weight (kg)	122 (92-144)	126 (105-140)	$p > 0.05$
Body Mass Index (kg/m ²)	42 (35-42)	44 (43-51)	$p > 0.05$
Glucose (mg/dL)	98 (89-172)	125 (100-147)	$p > 0.05$
Cholesterol (mg/dL)	209 (165-237)	185 (164-198)	$p > 0.05$
HDL (mg/dL)	60 (57-63)	48 (41-55)	0.011
LDL (mg/dL)	133 (84-182)	101 (82-126)	$p > 0.05$
Triglycerides (mg/dL)	93 (73-155)	143 (107-179)	$p > 0.05$
AST (IU/L)	16 (12-22)	15 (25-42)	$p > 0.05$
ALT (IU/L)	14 (13-25)	25 (20-30)	0.045
GGT (IU/L)	18 (15-21)	26 (23-50)	$p > 0.05$
FIB4 Score	0.84 (0.39-1.13)	0.81 (0.66-1.15)	$p > 0.05$

DISCUSSION

TGF-B2 gene expression was higher in the steatosis group than in the control group. This finding is interesting, as TGF-B genes have been related to fibrotic changes. In fact, TGF-B1 is known to have a central role in the development of liver fibrosis [17]. Also TGF-B2 is known to be an important fibrotic factor [18]. This increase in TGF-B2 is related to a decrease in its type 1 receptor (TGF-BR1 = ALK5). This finding has also been found in HCC cells [19]. Another change related to TGF-B family is the increase in Inhibin subunit beta A (InhBA). InhBA increase has been found in fibrotic and chirrhotic livers from rats [20].

Follistatin (FST344), which is also related to TGF-B family, is another gene that was found to be increased in patients with mild/moderate steatosis. FST344 has been found to be increased in patients with liver carcinoma and is related to clinical characteristics of bad prognosis and a higher tumoral size in patients with HCC [21-23].

Another interesting finding was the increase of genes that have classically been associated with HCC, such as IGF2 [24] or AFP. Also, genes that have recently been related to HCC, such as AREG and CK18, were increased in patients with mild/moderate esteatosis.

Insulin receptor (IRS2) which has also been related to liver tumors [25] was elevated in the study group. Genes related to metastasis, such as MMP7 and VEGFB were also increased [26].

Table 2. Comparison of genetic expression in control and mild/moderate steatosis group

Genes	p
ADIPOR2	0.028
TNFA	0.05
MMPT	0.046
KRT18	0.045
FST	0.028
TGF-B2	0.03
TGF-BR1	0.038
INHBA	0.044
INSR	0.024
IRS2	0.021
IGF2	0.011
VEGFB	0.029
IRF2	0.039
AFP	0.013
AFM	0.033

Finally, ADIPOR2, the adiponectin receptor gene expression, was also increased. Adiponectin is a cytokine secreted by adipose tissue that regulates glycemic and lipid metabolism. This protein has been related to metabolic disorders of the liver [27].

CONCLUSION

In summary, after studying the liver samples from patients submitted to SADI-S with mild or moderate steatosis we have found an increase in the expression of several genes that could be related to HCC development. In the future, we will study if these changes are reversible. Our aim is to collect liver samples after the surgery to analyze if the genetic alterations disappear with the bariatric surgery.

Department of Surgery, Hospital Universitari i Politècnic La Fe, Valencia, Spain

ABSTRACT

Combining liver transplant and bariatric surgery at the same time (simultaneous surgery) represents a therapeutical option that can improve, in rapid ways, the basal conditions of NASH and obesity, trying to reduce, in a significant manner, the negative elements attributed to both chronic-inflammatory diseases. Simultaneous surgery can ameliorate some complication intrinsic to transplant surgery, such as rejection, infection, or disease recurrence due to the steatosis. The main disadvantage of simultaneous surgery is the potential to duplicate or potentiate the complications, such as the infections due to leaks in the hepatic or gastric surgical area. Similarly, simultaneous surgery is an aggressive procedure where the patients must adapt to important changes that result from the addition of these two major techniques. In fact, patients undergoing liver transplantation have to modify their diet, especially in the first few months following surgery, and at the same time they must learn to use the new therapeutic arsenal that must be maintained life-long in order to avoid rejection of the new organ. Currently, few quality studies can recommend liver transplantation simultaneously to bariatric surgery. In this sense, it is evident that specialists in hepatology and obesity have to work as a team to develop prospective randomized studies and lay the foundations for this therapeutic option.

INTRODUCTION

At present, obesity is a worldwide epidemic. It is defined as a Body Mass Index (BMI) over 30 kg/m². In 2005, nearly a quarter of the world's adult population was overweighted (BMI $\geq$ 25 kg/m²), and approximately 10% of the population was obese [1]. By 2030, it is estimated that the projected burden of obesity will reach 2.16 billion overweighted and 1.12 billion obese individuals, representing 38% and 20% of the world's adult population, respectively [1]. Over the last decades the prevalence has been increasing mostly in Occidental countries, despite growing recognition of its harms and social preventive health programs [2, 3]. In 2014, it was estimated that 35% of men and over 40% of women were obese. By 2030, an estimation suggests more than half of the U.S. population will have a BMI $\geq$ 30 kg/m² [1, 2, 4].

In 2018 a consensus document from the First Spanish NAFLD meeting in Seville was published, entitled "Management of non-alcoholic fatty liver disease (NAFLD)". The result was a Clinical practice guideline [5], with some interesting data.

Non-alcoholic fatty liver disease (NAFLD) has become the most frequent cause of chronic liver disease in children and adults. NAFLD is associated with the global epidemic of obesity and metabolic syndrome [6-8], and is a growing cause of advanced liver disease [9, 10]. In the next few years, NAFLD and alcoholic liver disease will become the most prevalent causes of chronic liver disease in our countries.

The prevalence of NAFLD increases in parallel to the prevalence of metabolic syndrome and its components, especially obesity and diabetes mellitus (DM) [11-12].

Among patients with DM, the prevalence of NAFLD is estimated at 40 - 70%, and the prevalence of NASH is around 22% [13].

In the United States, cirrhosis due to non-alcoholic steatohepatitis (NASH) has become the second most common indication for the inclusion in the waiting list, and the third indication for liver transplantation (LT) [14-21]. This same trend is observed in the transplantation registries of other countries.

These patients usually have obesity-related comorbidities with an increased the risk of cardiovascular (CV) disease [14-22].

NASH will become the main indication for liver transplantation in the next decade. In patients with obesity and NAFLD who require transplantation, the indication is typically for decompensated liver disease [7]. Weight loss has been shown to decrease the progression of NAFLD [23]. Weight loss can result in improvements in liver fibrosis and hepatic steatosis [24].

Diet and exercise are the medical weight loss options, but the weight reduction obtained is around 10%.

Bariatric surgery (BS) is not usually performed in patients with cirrhosis; but several studies have shown its safety in patients with non-cirrhotic NAFLD and even NASH [25, 26]. In addition, it has been demonstrated that there is a significant improvement in both fibrosis and steatosis, with regression of fibrosis in 75% of patients and resolution of steatosis in 84% of patients two years after BS [27].

There are different techniques of bariatric surgery, although the most frequently performed are Roux-en-Y gastric bypass (RYGB) and sleeve gastrectomy (SG).

RYGB is considered by many authors the gold standard bariatric surgical procedure, but in comparison with other surgical approaches it has a higher risk of complications [28]. This is important when operating on a population of patients that have an inherently higher morbidity surrounding any surgical intervention. In addition, in the context of LT, the malabsorptive component of RYGB surgery may cause alterations in immunosuppression absorption [29], a situation that does not occur when an SG is performed [30].

The indications for bariatric surgery in the general population are: a BMI $\geq 35\text{kg/m}^2$ with obesity-related comorbidities, or a BMI $\geq 40\text{kg/m}^2$ [31]. But in the patient with advanced liver disease or who has already undergone a liver transplant, careful consideration is required.

The timing of surgery continues to be a debate: previous to LT, simultaneous with LT, or delayed after LT.

INTERNATIONAL LIVER TRANSPLANTATION SOCIETY (ILTS) AND OBESITY CONSENSUS

Recently, the International Liver Transplantation Society (ILTS) convened a consensus conference in Venice in 2018, with a global panel of expert hepatologists and transplant surgeons, to develop guidelines on key aspects of NASH in relation to liver transplantation [32].

Some questions were addressed through the critical review of the literature in different working groups to achieve a global consensus through some statements.

Below are the highlights, to focus next on the surgical aspect.

1. Are the results of liver transplantation different in obese patients?

The outcome of LT in patients with NASH-related cirrhosis with or without hepatocellular carcinoma does not differ from that of other liver transplant etiologies as posttransplant survival is similar [14-22, 33-37].

2. Concerning the natural history of cirrhotic patients on end-stage liver disease, is it different in NASH-related from other etiologies?

Patients with NASH-related cirrhosis have increased CV morbidity and mortality compared to patients with cirrhosis of other etiologies. Patients with NASH cirrhosis have lower mortality rates in the compensated state (Child Pugh A) but similar mortality in the decompensated state (Child Pugh B and C) compared to HCV-related cirrhosis [38-43].

3. Should this increased CV risk be assessed differently in the transplant-listing evaluation?

It is described and demonstrated that liver transplant candidates with NASH should be considered at high risk of developing CV events before and after transplantation. The resulting accumulation of CV risk factors should be carefully evaluated by a multidisciplinary team (including a cardiologist and an anesthesiologist at least). The approach to the pre-LT CV assessment will be the same as other etiologies [21-22, 34, 44-53]. There is not enough evidence to recommend a specific CV risk algorithm for NASH patients undergoing LT evaluation. The stress tests should be of interest.

4. *Is it recommended a particular management of comorbidities in the obese candidate for LT?*

A multidisciplinary approach is always recommended to establish a risk minimization plan, with an appropriate screening for hypertension, diabetes, and dyslipidemia. Medical optimization in NASH-patients with indication for LT is strongly recommended [54-61].

5. *What therapeutic strategies are recommended on the NASH patient in the waiting list for LT?*

Cardioselective beta-blockers and statins can be considered in patients with Child A-B NASH-related cirrhosis and CV comorbidities [62-67].

Moderate exercise is recommended with the double objective of losing weight and improving muscle mass. Prehabilitation programs are increasing in different centers, based on the impact on postoperative recovery and morbimortality [68-72].

6. *Can obesity contraindicate LT?*

Class I-III obesity alone is not a contraindication for liver transplantation. However, in the presence of medical comorbidities, particularly concurrent diabetes, rigorous patient selection is strongly recommended [73-84].

Most studies investigating the effect of obesity on posttransplant survival have reported similar posttransplant patient survival across all BMI categories in the absence of concurrent comorbidities.

But most of these studies have limitations regarding DM-specific data, ascites status for corrected BMI, etc. In addition, most studies are retrospective and/or include an unmatched patient population.

Optimal control of comorbidities such as obesity and diabetes before transplantation is difficult with medical treatment. Bariatric surgery should be considered as a good tool to achieve these targets.

7. *Bariatric surgery in obese candidate for LT: What type of BS is the most appropriate? When is the optimal timing for bariatric surgery: before, during or after liver transplantation?*

We will focus this chapter on these questions, with a small review on bariatric surgery.

BARIATRIC SURGERY IN THE SETTING OF LIVER TRANSPLANTATION

Bariatric surgery is a safe and effective treatment for severe obesity. There are many randomized controlled trials and cohort studies that demonstrates this [85-90]. BS has a beneficial long-term impact on the risk of mortality [91-93].

After BS, obesity comorbidities such as diabetes and metabolic syndrome, are often improved or resolved [85, 89].

RYGB (Figure 1A) was traditionally considered the “gold standard” surgical approach because of its short-term weight loss results and its long-term durability. Until 2014, 79.5% of bariatric cases were RYGB [94].

Gastric banding (GB) use is decreasing because of its modest weight loss and poor long-term weight loss durability [95].

The use of SG (Figure 1B) has increased significantly due to lower complication rates with comparable weight loss and resolution of obesity associated conditions [96].

Type of Bariatric Surgery

BS in the context of transplantation has some special considerations. We only compared SG to RYGB.

A. Roux-en-Y gastric bypass

B. Sleeve gastrectomy

Figure 1. A) Roux-en-Y gastric bypass is a mixed bariatric surgical procedure: restrictive and malabsorptive. B) Sleeve Gastrectomy is a restrictive bariatric surgical procedure, with no malabsorptive component.

Efficacy of GB is limited to case reports. Disadvantages include placement of a foreign body in an immunosuppressed patient with a risk of gastric wall erosion and relative difficulty to endoscopic access if needed.

In many studies, the most common procedure has been SG, up to 100% in some series [97-101]. There are some advantages compared to RYGB:

- technical surgical advantages: minimal additional operative time and no intestinal anastomosis
- postoperative immunosuppression (IS) therapy: it does maintain adequate immunosuppression levels without altering the absorption of medications
- endoscopic procedures: allows endoscopic access to the biliary system for management of posttransplant biliary complications.
- inaccessibility of the gastric remnant if variceal bleeding were to develop when RYGB is performed

Previous reported series have demonstrated steady and gradual EWL% (percentage of excess weight loss) in SG procedure. Takata et al. included both RYGB and SG procedures, SG reported acceptable EWL% (25 - 75%) but lower compared to RYGB [102].

NASH patients constitute a group of increasing LT candidacy. In these patients with metabolic syndrome and other obese-related comorbidities, bariatric prior to transplant or simultaneous LT and BS combined approach might be reasonable in order to have an impact on these risk factors. This should improve both pre and posttransplant outcome.

From Mayo Clinic group in Rochester, one prospective study comparing LT alone to LT-SG demonstrated that the LT + SG group maintained a significantly higher percentage of total body weight loss after 3 years of follow-up. They also had a lower prevalence of hypertension, insulin resistance, and hepatic steatosis and required fewer antihypertensive medications and lipid agents at last follow-up [103].

TIMING OF BARIATRIC SURGERY

Bariatric Surgery before Liver Transplantation

BS in NASH and NAFLD patients has been shown to be effective in both weight loss and improvement in liver pathology [26-27].

In the cirrhotic patients that we find in this group, factors as platelet count, INR, bilirubin, and MELD score can impact on outcomes during BS, with an increased risk and severity of postoperative complications.

Appropriate patient selection may allow pre-LT patients to undergo SG safely. Obesity in LT patients do not increase mortality or worsens graft survival [73]. But, a lower BMI at the time of LT could decrease the risk of wound complications in the short-term and recurrent NASH in the long term [104].

BS before LT seems appropriate for patients with low-MELD score. Particularly with low or no portal hypertension to reduce post-BS morbidity and mortality. This will potentially improve the outcome of LT. Takata and Lin [102, 105] reported significant improvement in metabolic comorbidities, but rates of postoperative complications were significantly higher compared to the general population. But complication rates up to 35% were reported in patients incidentally diagnosed with cirrhosis after BS [106]. This timing could be a good option in low-MELD score patients without portal hypertension.

Simultaneous Liver Transplantation and BS

In 2013, Mayo Clinic published a prospective series of patients who underwent combined LT and SG [107]. In 2018, Mayo Clinic updated their prior experience on long term outcomes [103].

Patients enlisted in the study were all adult patients listed for LT since 2006 with BMI > 35 kg/m² (corrected for ascites). These patients were enrolled in an aggressive weight management protocol consisting on dietary education provided by an experienced transplant dietician in subsequent visits until transplantation or achievement of goal weight.

Patients were also evaluated by the same transplant surgeon at the initial and at each subsequent visit to assign a specific weight loss goal (generally BMI < 35 kg/m²), to further emphasize the long-term benefits of weight loss and to assess progress with weight loss.

Patients were asked to:

1. follow a calorie restricted diet, generally 1200 – 1400 kcal for women and 1400 – 1600 kcal for men,
2. keep an intake record including type, amount and calorie total and bring record to follow-up visits,
3. weigh and record at least once per week and
4. gradually increase activity to 30 – 40 minutes/day, which could be achieved in multiple segments through the day, with walking being the primary recommendation, modified based upon specific patient limitations.

Patients with severe obesity who were unsuccessful with achievement of pretransplant target weight (BMI < 35 kg/m²) who also had a MELD score high enough to allow them to proceed to transplantation underwent a combined liver transplant plus sleeve gastrectomy (LT-SG).

These patients were assessed by the bariatric surgery team and completed the standard bariatric surgery education. All seven LT-SG were performed using deceased donors, with a caval sparing hepatectomy and a duct to duct biliary anastomosis. The SG was performed by an experienced bariatric surgeon following completion of the LT utilizing a 9 mm endoscope placed along the lesser curve of the stomach. A combination of 45-mm 4.8 and 60-mm 3.5 Endo-GIA staple loads were used to resect the antrum and greater curve. Care was taken to leave a small amount of cardia in place in order to avoid injury to the esophagus. The staple line was oversewn using a running 3-0 PDS suture and directly visualized from the lumen of the stomach to ensure hemostasis upon completion, utilizing the previously placed endoscope.

Post-LT management included follow-up visits with the dietician, being counseled on a low-calorie diet plus exercise. Those who underwent combined LT plus SG were seen by the dietician and the bariatric surgery team (surgery, endocrinology and psychology), with the appropriate diet and standard of care in these patients,

In the first report in 2013, obese patients who were unsuccessful with a non-invasive weight loss protocol prior to LT were offered a SG simultaneous with LT (LT-SG) (n = 7). This LT-SG group was compared to a group of obese patients who achieved weight loss via a noninvasive pre-LT weight loss program and underwent LT alone (n = 30). LT-SG group had a MELD of 32 (range 11-40) at time of procedure and 4 out of 7 had NASH as etiology of cirrhosis. Mean operative time was increased by 38 minutes in the LT-SG group and no intraoperative complications were observed. As compared to the non-invasive obesity management, combined LT-SG demonstrated higher resolution of diabetes (100% vs 65.7%) and lower BMI at last follow-up (29 kg/m² vs 36 kg/m²). Two post-operative complications (28.5%) were related to the SG: one staple line leak and one patient with excess weight loss. Heimbach et al. conclude that LT-SG is technically feasible, although not without risk [107].

There are two additional case series/reports of LT-SG from Italy and Israel with similar results: considerable weight loss and no significant perioperative complications [108-109]. But these two articles have two important shortcomings: a short follow-up and a small sample size.

The 2018 publication of the Mayo Clinic provided an update on long-term outcomes for patients who were already enrolled in the 2013 study, plus new recruited patients thereafter [103].

The methodology used with respect to the inclusion criteria was the same as before, but the prevalence of NASH-related cirrhosis is growing over the years. Despite this increasing prevalence, in the US these patients are less likely to be placed on the waitlist, and exhibit higher waitlist mortality, demonstrating that obese patients are disadvantaged on the transplant waiting list [110]. Even that recent reports have noted no difference in patient or graft survival for these patients [73, 75, 111-113]. From the previous Mayo Clinic report in 2013, the aim of this 2018 update was to describe longer-term outcomes, including the dynamics of weight, impact on metabolic outcomes, and quality of life, among these patients after a mean follow-up of 5 ± 2.4 years. They have also provided perioperative and short-term outcomes for the entire cohort of LT + SG patients.

Only patients who were at least 3 years follow-up posttransplantation were included in the long-term outcome analysis. Weight and BMI changes were assessed using the percentage of total body weight loss (%TBWL), frequency of a 10% total body weight loss, and the percentage of excess BMI loss (%EBMIL; where BMI = 25 is the normal value). At last follow-up, Adult Treatment Panel (ATP) III criteria was used to assess for metabolic syndrome [114].

It was also updated the evaluation of diabetes (serum determinations of insulin, Homeostasis model assessment index for insulin resistance (HOMA-IR) [115] was calculated and Hemoglobin A1c (HbA1c) was documented [116].

Hepatic steatosis, defined by ultrasound, computed tomography or biopsy, was also evaluated.

And the questionnaire SF-12 version 2 was used to assess quality of life among patients through a phone interview.

There were 74 patients enrolled with 45 undergoing LT alone and 29 undergoing a combined LT + SG. The mean BMI at the time of transplant for the LT-SG group was 47 kg/m² (mean weight at LT of 135 kg) with a reduction in BMI to 31 kg/m² at last follow-up.

The complication rates were the same as in the previous study. Complications related to SG included one staple line leak, one excess weight loss (stabilized), and two reflux that stabilized at last follow up.

In order to determine the long-term impact of this protocol, only patients with at least 3 years of posttransplant follow-up are included. At three years follow up, LT-SG patients maintained a significantly higher percentage of total body weight loss (%TBWL) when compared to obese LT patients with no combined procedure (LT $3.9 \pm 13.3\%$ vs LT-SG $34.8 \pm 17.3\%$; $p < 0.001$) (Table 1).

Overall, there was no significant difference observed in the LT alone group between the BMI at listing and the BMI at 3 years (40.06 ± 2.99 vs. 38.53 ± 6.53 ; difference -1.52 ± 5.46 ; $P = 0.138$) (Figure 2).

In reference to the metabolic syndrome, as shown in Table 2, patients in the LT-SG group had at long term a lower prevalence of hypertension, insulin resistance and hepatic steatosis, and required fewer lipid agents at last follow-up.

In summary, LT-SG group have more effective and more durable weight loss as well as fewer metabolic complications at last follow up when compared to medical weight loss interventions combined with LT.

Table 1. Bariatric parameters and weight dynamics post-surgery

SEBMI	Listing	Transplant	4 months	1 year	2 years	3 years

About the Quality of Life questionnaire, it was a lack of reply, with an overall response rate of 57%. The results of the SF-12 questionnaire showed no significant differences between the two cohorts in any of the categories available.

Bariatric Surgery after Liver Transplantation

This option could be considered since weight loss decreases the risk of recurrent steatosis in the liver graft.

There are few case series with small sample size with a retrospective approach [117-121]. It has been reported a good %EWL and improvement in obesity comorbidities.

Surgeons usually find adhesions and bleeding issues due to reoperation. However, BS after LT is an option for those who develop obesity after transplantation, particularly in patients who were not obese before transplantation.

BS after LT has no impact on comorbidities during the peritransplant period. It has the advantage of a proper selection of patients requiring BS in an elective way, but disadvantages include difficult access to the abdomen and high postoperative morbidity and reoperation rates reported in the literature.

CONCLUSION

NASH is today in 2019 the second major etiology of liver transplantation in the United States, and is expected to become the first in a short time [122]. Obesity comorbidities have a negative impact on graft and patient survival.

Besides, recurrent NAFLD develops in 30 - 60% of patients following LT for NAFLD [123]. This high recurrence rate forces to take preventive measures.

Patients with morbid obesity have more infectious and surgical complications after LT [124-125], and an additional BS may also complicate posttransplantation period.

BS in the peri-transplant period can cause a significant weight loss and a substantial decrease in the incidence of obesity comorbidities, such as diabetes and NASH. This leads to decrease patient morbidity and increase both patient and graft survival.

SG should be considered as a first surgical bariatric option in obese LT patients. SG is a restrictive weight loss procedure that provides durable weight loss results with significant improvement in obesity related comorbidities such as diabetes mellitus, hypertension, and obstructive sleep apnea. In addition, compared to RYGB, there are no changes in IS therapy and the access to the biliary system is maintained.

Bariatric surgery seems to be feasible and effective in morbid obese patients in the setting of liver transplantation, assuming a higher postoperative complication rate.

Bariatric first or concomitant approach might be reasonable for NASH patients who have pre-LT comorbidities including metabolic and CV problems that may complicate the post-transplant period. The optimal type of BS remains unclear, but SG seems to be the preferred approach by most surgeons [97-99, 103].

The optimal time of BS in relation to liver transplantation has not yet been determined.

To date, there are no studies comparing different timing of BS in relation to liver transplantation.

ABSTRACT

The best result so far in the non-surgical treatment of NASH has been obtained with diet and physical activity supervised by professionals, this promotes the reduction of body weight and metabolic stabilization. The use of pharmacotherapy is only for patients with NASH in very specific contexts. For example, Pioglitazone and vitamin E can be used, since they have shown acceptable results according to various guides and consensus. Novel medications have shown encouraging results with positive effects in basic science studies or small clinical trials; studies with a larger number of patients and a more rigorous methodology are needed.

Keywords: medical-treatment of NASH, diet, exercise, clinical trials, experimental drugs, pioglitazone, vitamin E

INTRODUCTION

The prevalence of Non-Alcoholic Fatty Liver Disease (NAFLD) has peaked in the last 30 years. This worldwide epidemic has drawn the attention of diverse research groups that, by

* Corresponding Author's Email: raulber@yahoo.com.

delving into the pathophysiology of the disease, have revealed the complex details of the disease. In its original description, the histopathological resemblance to alcoholic steatohepatitis was highlighted [1]; however, the patients with NAFLD have low alcohol consumption: less than 30 grams per day in men, and less than 20 grams per day in women [2]. Ever since Ludwig's article was published in 1980, knowledge about NAFLD has increased. Its physiopathology has been related to diverse factors: high-fat and high-carbohydrate diet, extreme sedentarism, intestinal dysbiosis, insulin resistance, and the activation of macrophages and pro-inflammatory agents, to name the most researched ones.

The notable increase in knowledge about this disease allows us to delve into the physiopathological steps that represent multiple opportunities for therapeutic action. This recent research interest is one of the reasons why the amount of therapeutic options nowadays is so large. However, many of these options come from preliminary case reports, mostly anecdotal, with poor methodology and rarely reproducible.

This disease's complexity and its multiple comorbidities compel us to consider the treatment of NAFLD in a broader context, since this is not just a liver disease. In fact it is a systemic one, and it is one of the components of the Metabolic Syndrome (MetS). It is estimated that up to 90% of patients with NAFLD have at least one associated component of MetS, usually obesity, followed in frequency by diabetes mellitus type 2 (DM2), dyslipidemia and arterial hypertension. It is recognized that as a patient gathers more components of the MetS, her risk of suffering NAFLD is greater [3]. This explains why commonly these patients require multiple treatments aimed not only at preventing the progression of liver disease, but also at promoting metabolic stability and at limiting the risk of cardiovascular disease, the main cause of death among patients with NASH. Each patient with NAFLD has a clinical profile of its own that makes him different from others, and therefore requires an individualized treatment; what today is known as patient-centered medicine. This is a compelling reason that explains why, today, the possibility of a standardized treatment for patients with NAFLD is remote, and it is an incentive to research into personalized medicine alternatives.

Another factor to have in mind, for therapeutic purposes, is the natural evolution of the disease. Most patients affected by NAFLD have a good prognosis if they remain in the steatosis stage, or Non-Alcoholic Fatty Liver (NAFL). Luckily, these are the majority and an effective change in lifestyle (weigh reduction diet and physical exercise) will suffice to accomplish metabolic stabilization, and even reverse steatosis.

The phenotype of the patients with NASH is different from patients with NAFL stage. These patients have a greater tendency to progression; particularly those in whom fibrosis has started have the worst prognosis for the having liver cirrhosis [4]. Therefore, the efforts to find a useful drug have focused mainly on the control and regression of NASH's characteristic inflammation and fibrosis.

Save for a few exceptions, drug therapy is advised only in patients with biopsy supported NASH diagnosis [5].

The most relevant controlled clinical drug trials have a success rate of less than 50%; therefore, major regulatory agencies have not approved any pharmacological treatment for NASH. Only vitamin E and pioglitazone have shown a limited beneficial effect in very specific contexts; nevertheless, they have the disadvantage of relevant side effects. There is another group of drugs whose reports initially showed good results; however, these were not confirmed when more stringent trials were undertaken. Finally, there is a very promising third

group of drugs that are currently in phase II and phase III studies, they act in different points of the complex pathophysiology of NASH and a lot is expected from them in the years to come.

So far, the best results in the treatment of patients affected with NAFLD have been achieved with significant lifestyle changes. A weight reduction diet combined with physical activity can reduce steatosis, inflammation, and even liver fibrosis. Additionally, lifestyle changes favours metabolic control and stabilization of the comorbidities that frequently accompany NAFLD.

WEIGHT LOSS

Although most patients with NAFLD are overweight or obese, there are also cases of non-obese patients, this variety is known as “*lean NAFLD*”. In these patients the presence of other components of MetS is common [6]. This is the reason most of them benefit from weight reduction, which favours metabolic control and limits hepatic steatosis [7].

The effectiveness of weight reduction has been demonstrated in patients with NAFLD and corroborated with liver biopsies before and after the intervention. A loss of 7% initial body weight achieved a reduction of ≥ 2 points in the NAFLD Activity Score (NAS), with an improvement of fibrosis of up to 50%. When the weight reduction reached $\geq 10\%$, the improvement or resolution of fibrosis went up to 80% [8]. In general terms, a weight reduction $\geq 3\%$ is enough to significantly reduce steatosis; a weight loss $\geq 7\%$ has an impact on the development of NASH, decreasing the inflammation and hepatocyte ballooning, and a loss $\geq 10\%$ can reduce fibrosis.

Due to the current absence of an approved pharmacological treatment for patients with NASH the fundamental pillars of therapy are lifestyle changes, based on a personalized diet and supervised physical activation. Jointly these promote not only weight reduction, but also metabolic stability and, therefore, a significant reduction in steatosis, inflammation, and hepatic fibrosis. Despite good results, this change in habits is seldom long lasting, and difficulties to treatment attachment remain a problem in the management of these patients.

DIET

The so-called western diet has gradually become omnipresent around the world, replacing traditional diets. This diet is based on the consumption of large portions of fast food; an excess of saturated fats and refined sugars characterizes it. Of the later fructose stands out, which one is used indiscriminately in the food industry and causes hepatocellular damage through different routes [9].

A first goal of a weight loss diet should be to reduce caloric intake. Initially patients with overweight and obesity should be advised to reduced saturated fat and refined sugars, the recommended ratio of nutrients is of approximately 20% protein, 30% fat (predominantly monounsaturated), and 50% carbohydrates. The average fiber intake should be of 25-35 gr. per day. It is very important to let the patients know that they should avoid eating processed foods, particularly sweet drinks because of their high fructose content [10, 11].

The best example of a diet with good results is the Mediterranean diet. It comprises an abundant consumption of fish and poultry as proteins sources, lots of vegetables and fruits, moderate portions of cheese and cereals, olive oil and moderate wine consumption; additionally it implies a significant restriction of red meat, snacks and desserts [12, 13]. The main features of the Mediterranean diet are high-fiber and antioxidant content, as well as properly balanced portions lipid and unrefined sugars. Additionally, the diversity of suggested foods favours greater acceptance and adherence, unlike the irregular compliance that characterizes hypocaloric diets [14].

Ketogenic diet also has been proposed as treatment for NAFLD. It became popular several years ago in morbidly obese patients who were to undertake bariatric surgery, because of its rapid effect of weight loss. It is based on carbohydrate restriction to induce a higher consumption of body fat deposits as main energy source. In other words, it shifts metabolism from a glycolytic state to a lipolytic one as a consequence of carbohydrate shortage, and it uptakes fat as the main source of energy. However, even though this diet has been shown to contribute to body weight loss, it has been questioned for inconveniences such as favouring constipation and a poor attachment of patients due to multiple food restrictions. Recently two relevant facts emerged; the first, that promoting a rapid weight loss could favours an increase in hepatic steatosis, and, the second, that this diet requires vitamin and mineral supplementation [15].

Due to the frequent comorbidities that condition diverse clinical profiles in patients with NAFLD and the metabolic complexity represented by the dietary adjustment, The Mexican Consensus on NAFLD recommends dietary management of these patients to be customized and implemented by a nutritionist, who most consider among other things, the average energy expenditure of each patient [5].

EXERCISE

Physical activity favours the consumption of calories, and a properly executed exercise routine offers benefits in metabolic control and induces weight loss through the mobilization of fat deposits. Biochemical effects of exercise are many fold, among the most notable are reducing insulin resistance, improving lipid metabolism, endothelial function, blood glucose levels, and reducing pro-inflammatory activity, all are common alterations in the patient with NAFLD [16].

A recent systematic review revealed that exercise by itself, even without significant weight loss, can reduce hepatic steatosis in 20% to 30%, regardless of whether being aerobic or resistance exercise [17]. Notwithstanding this, exercise as the sole therapeutic measure is not enough and should be complemented with a proper diet to promote weight loss, the most effective intervention so far [18]. In adults the WHO recommends a moderate aerobic exercise routine of between 150 and 200 minutes per week [19]. As is the case for diet, a professional who advises the patient on the intensity and type of exercise to be performed by each patient should supervise this routine.

PHARMACOTHERAPY

Pharmacological treatment is not for all patients with NAFLD, it is crucial to establish that it is only indicated in patients with NASH and evidence of fibrosis ($F \geq 2$), or in those with a higher risk of progression (DM2, MetS, or persistently elevated ALT) [5]. The ideal treatment should address not only liver damage, but also the associated metabolic alterations: DM2, obesity and dyslipidaemia. Additionally, it should consider cardiovascular risk, since these comorbidities confer an increased risk of disease progression and premature death. Regarding the liver, the ideal drug should reduce hepatic inflammation, hepatocellular damage, correct insulin resistance, and have anti-fibrotic effects [20, 21].

As stated above, to date there is not a single effective and safe pharmacological treatment for all patients with NASH. Therefore, the proposed options are many folds, with very different mechanisms of action and contrasting results.

For the objectives of this review, we will divide the most relevant drugs into three groups:

- A. Drugs with some favourable effect.
- B. Drugs that are discouraged.
- C. Promising drugs in pharmaceutical development

A. Drugs with Some Favourable Effect

Fundamentally two medications, pioglitazone and vitamin E, may be indicated in very specific contexts. The maximum level of histological improvement they have is close to 50%. Both have been evaluated in several studies; the PIVENS study stands out for its good methodology, it included patients with NASH without cirrhosis or diabetes, and obtained acceptable results [22].

Pioglitazone

This drug belongs to the thiazolidinedione family of drugs and is a treatment for DM2. It acts as a *PPAR- γ* receptor agonist with very interesting and diverse pharmacological effects: improvement of insulin sensitivity in adipose tissue, favours the deposit of free fatty acids in adipose tissue instead of in the liver, increases the production of adiponectin, and favours beta-oxidation of fatty acids in the hepatocyte; additionally it might have anti-inflammatory and anti-fibrotic effects [23].

Several adequately controlled trials, with follow-up periods of up to 18 months support its indication in some patients with NASH with or without DM2. They have reported improvement in insulin resistance and aminotransferase levels. Histologically, a significant decrease in steatosis, inflammation and ballooning injury has been shown in hepatocytes. Also, there is an improvement of fibrosis in variable ranges, with a 73% NAS improvement in treated patients vs 24% in those who received placebo; resolution of NASH has been reported in 47% to 51% of treated patients [22, 24-26].

It is important to note that thiazolidinediones also decrease in cardiovascular mortality and cerebrovascular events [27, 28].

This drug is usually well tolerated, although the reported side effects should be considered and discussed with patients. The most common of these is an increase in body weight [22, 26]; others are a putative, and controverted, such as an increased risk for bladder cancer [29, 30] and hip fracture in postmenopausal women due to decreased bone density [31].

Vitamin E

Because of its antioxidant effect, vitamin E has been proposed as an effective option for patients with NASH. Some studies have shown a reduction in steatosis and inflammation, even a reduction in hepatocyte ballooning degeneration [22] the latter was seen in a study of children [32]. However, no effect on fibrosis or resolution of NASH has been reported. Initially it was not recommended for patients with diabetes, however later studies confirmed its utility in them [33].

Like in the case of pioglitazone, this drug also has relevant side effects. The most important is an association between high doses of vitamin E (> 400 UI per day) and mortality [34]. Others adverse effects are an increased risk of prostate cancer and haemorrhagic stroke [35].

Other drugs have early positive results at the laboratory level or in small patient groups. Nevertheless, we lack good quality controlled clinical trials that supports its prescription in patients with NASH. However, some of them could be used to treat some of the frequent comorbidities; this is the case of liraglutide [36-37] and pentoxifylline [38]; this group complements with others like silymarin, silybin-phosphatidylcholine, pirfenidone, ademetonine and probiotics. We expect controlled clinical trials to be carried out in the coming years to confirm their effectiveness or to disqualify their use. For now the evidence is insufficient and does not support the prescription to treat patients with NASH [5].

B. Drugs That are Discouraged

In this group are those drugs that initially had good expectations, but whose effectiveness was rejected in subsequent studies, therefore they are not indicated in the treatment of NASH. Among the best known are metformin [39], ursodeoxycholic acid [40, 41], omega-3 fatty acids [42], and fibrates [43, 44].

As previously mentioned, these drugs were launched with quite optimistic reports regarding their therapeutic utility; however, in these cases there is enough clinical evidence from clinical trials and meta-analysis that reject their benefit, or that failed to reproduce the initial results. Therefore, they are not relevant for treating NASH.

Some of these drugs can be used in patients with NAFLD for the management of other comorbidities, such as DM2 or dyslipidemia, but not for fatty liver.

C. Drugs in Development

There is a growing interest of the pharmaceutical industry in developing new medicines with good and definitive results in the treatment of NASH. Currently there are many

molecules in development, some of them in stages as advanced as phase II and phase III, with surprising initial results. They are especially effective in stopping and reversing inflammation and fibrosis. The following is a selection based on their potential benefit and stage of development.

Obeticholic Acid

This is a semisynthetic derivate of chenodeoxycholic acid that works as agonist of farnesoid X receptor (FXR). It reduces the synthesis of bile acids in the liver, as well as lipogenesis and gluconeogenesis, and it stimulates beta-oxidation. In the FLINT study [45], compared obeticholic acid with placebo for 72 weeks; patients in the intervention arm had significant improvement in steatosis, inflammation, hepatocyte ballooning degeneration and fibrosis; a reduction in NAS ≥ 2 was obtained; higher than that observed in those who received placebo (45% vs. 21% RR 1.9 was achieved; 95% CI 1.3 - 2.8, $p < 0.0002$). A phase III study is currently underway to evaluate its impact on fibrosis. In the same way, similar analogues are in development. The main side effect that has been reported with this drug is pruritus, in up to 23% of those who received it, increased LDL and decreased HDL also have been observed.

Cenicriviroc

It is an antiretroviral that inhibits receptors 2 and 5 of chemokine CC, its use in HIV patients is also investigated; in preliminary studies it has shown good anti-inflammatory and anti-fibrotic effects. In the CENTAUR study [46], an interesting design with a two-year follow-up was implemented. The final results did not reveal significant changes in steatosis or ballooning injury; however, it is noteworthy to say that there was an improvement in fibrosis without NASH worsening and this one was well tolerated.

Elafibranor

It is a *PPAR- α* agonist with anti-inflammatory effect. Metabolically its main characteristic is to improve insulin sensitivity and glucose levels as well as to stabilize lipid metabolism. The GOLDEN-505 study showed a better effect in patients with basal NAS ≥ 4 and receiving a higher dose (120mg). In these patients improvement in aminotransferases, serum lipids, glucose and inflammatory markers with significant decrease in fibrosis stage were shown. Elafibranor was well tolerated, improved patient's cardiometabolic risk profile, but induced renal failure in seven patients [47].

Selonsertib

Preliminary reports in a murine model indicate that this inhibitor of the regulatory kinase of signal of apoptosis (ASK1) that promotes liver fibrosis has a good anti-fibrotic effect. This effect was confirmed in a controlled clinical trial that showed the best results among those who received a dose of 18 mg for 24 weeks, resulting in a reduction of ≥ 1 in the stage of fibrosis in 43% of the patients, and in 30% of those who received a lower dose (6mg) [48]. It was also studied in combination with GS-0976 an Acetyl-coA carboxylase (ACC) inhibitor to block the synthesis of fatty acids and reduce steatosis, with good results confirmed by Magnetic Resonance proton density fat fraction (MRI-PDFF) [49]. The phase III trial STELLAR 3 and 4 currently investigates its safety and effectiveness [50].

Emricasan

This drug inhibits caspase and has an anti-apoptotic effect. Preliminary reports found encouraging results with good anti-fibrotic effect in murine models. Currently phase II studies are running in patients with NASH and fibrosis [51].

Aramchol

This drug is a combination of arachidonic and cholic acids, it reduces the synthesis of fatty acids and triglyceride deposits and promotes the intracellular elimination of cholesterol. In a 3-month follow-up study Magnetic Resonance Spectroscopy confirmed that it effectively reduced hepatic steatosis. The drug was well tolerated and no significant side effects were reported [52], a phase IIb study is currently underway [53]. Aramchol has been granted a Fast Track designation status by the FDA for the treatment of NASH.

Combined Treatments

The inherent complexity of the NAFLD's pathophysiology suggests that it is unlikely that a single drug will achieve the best result. Hence, the individualization of treatment through the combination of drugs that allow us to intervene at different metabolic levels is required to stop the progression of the disease and reverse the present damage.

Currently there are few reports of this mixed therapy. An example is the combination of Selonsertib with Sintuzumab, reported by Loomba in a small group of patients; it showed that Sintuzumab achieved an improvement of ≥ 1 in fibrosis stage when combined with Selonsertib (6mg) in up to 40% of patients, compared with only 13% of those who were allocated to Sintuzumab alone [54].

There are other reports for the combination of vitamin E and vitamin C, in theory this dual therapy has the potential to reduce hepatic fibrosis [55]. Also, the combination of sitagliptin and losartan in a murine model was able to inhibit progression of disease [56].

These reports are preliminary and the currently available results for these combinations lack enough evidence to support its clinical use. Controlled design studies with high quality scientific evidence in larger groups of patients are necessary to have solid clinical claims.

CONCLUSION

The alarming increase in the worldwide number of patients with NAFLD demands drugs that offer useful healing alternatives. However, since this is primarily a metabolic disease (associated with other components of the MetS) the variability of its clinical phenotypes is widespread and this limits the use of a universal drug in all patients. On the other hand, the better knowledge of the multiple and complex pathophysiology of this disease has allowed to develop multiple therapeutic proposals with encouraging results. However, until now, none of them has been approved by the main regulatory agencies.

The best result so far has been obtained with diet and physical activity supervised by professionals, this promotes the reduction of body weight and metabolic stabilization. Both interventions are recommended in patients with NAFL and with NASH.

The use of pharmacotherapy is only for patients with NASH in very specific contexts. Pioglitazone and vitamin E can be used, since they have shown acceptable results according

to various guides and consensus. Other medications that have been proposed in preliminary studies, did not confirm their apparent benefits when subjected to more rigorous research methods. Therefore, today they are not recommended for the treatment of NASH; this is the case of metformin, omega-3 fatty acids and ursodeoxycholic acid.

Other novel medications have shown encouraging results with positive effects in basic science studies or small clinical trials; studies with a larger number of patients and a more rigorous methodology are expected to confirm their usefulness. Pirfenidone, liraglutide, silymarin, and probiotics are the most relevant of this group.

Finally, there is a very interesting group of drugs currently undertaking formal studies, with optimistic their initial results. The most relevant are obeticholic acid, cenicriviroc, elafibranor, selonsertib and aramchol. Almost all of them are in phase II and III studies, whose final reports are expected in the coming months.

Given the complexity of this disease, and the diverse clinical scenarios that each patient represents, combined treatment of two, or more drugs is emerging as the most viable therapeutic strategy. For now, in general terms, we hold that diet and exercise have proved useful in most cases and that the future with drug therapy is optimistic. Most likely we will have to combine them depending on each patient comorbidities. That is, we will have to make a suit tailored to each of our patients to achieve metabolic control, stop the progression of the disease, and reverse established liver damage as much as possible.

Chapter 317

THE USE OF GROIN FLAP FOR UPPER EXTREMITY COVERAGE IN ELECTRICAL BURN PATIENTS: EVIDENCE-BASED CASE REPORTS

Nathania Pudya^{*}, Aditya Warhana and Erythrina Permatasari

Division of Plastic Surgery, Department of Surgery, RSUPN Dr. Cipto Mangunkusumo,
Universitas Indonesia, Jakarta, Indonesia

ABSTRACT

Electrical burn injuries commonly occur in the extremities, particularly on the wrists, forearms, and hands. In high-voltage burns, the injury extends deeply and damages the underlying tissue, resulting in tissue ischemia and subsequently, a high probability of extensive tissue necrosis. In electrical burn injuries, nonvital tissue debridement and adequate defect closure determines the outcome of limb salvage. Clarification of the advantages of groin flap use for soft tissue defect closure is required to assist medical practitioners in deciding if groin flap should be considered as an option for upper limb reconstruction due to electrical burns. Two cases of electrical burn injuries to the extremities with two-stage reconstructive surgery using groin flap were reported. We questioned clinically whether a two-stage surgical method affected the morbidity of patients with electrical burns and investigated the correlation between the type of flap harvesting (delayed and non-delayed groin flap) and flap vitality. We also performed a literature search for relevant information regarding the use of groin flap in electrical burns injury using PubMed, ClinicalKey, and Google and initially identified 56 articles. After screening, the application of inclusion and exclusion criteria, and full-text reading, the three remaining articles were appraised in terms of validity, importance, and applicability. According to the literature, the timing of the reconstruction did not appear to affect flap survival and outcome. Moreover, fasciocutaneous flaps are relatively thin, making them ideal for coverage in regions with exposed tendon and bony structure. One study has revealed that the use of fasciocutaneous flaps to cover defects of an acutely burned hand showed a low infection rate comparable with that of muscle flaps, despite the argumentation of a greater susceptibility to infection in comparison to muscle flaps due to a comparatively inferior vascular plexus. No evidence was found from our search

^{*} Corresponding Author's Email: nathaniapudya@gmail.com.

of global literature indicating whether the time of flap harvesting affects flap vitality. In conclusion, the use of groin flap as distant pedicle flaps provided an alternative in cases where free flap reconstruction was impossible. The pathophysiology of vascular occlusion causes progressive necrosis of tissue in electrical burn injuries unrelated to the timing of reconstructive surgery. It is critical to debride nonvital soft tissue without jeopardizing the vital structures underlying the burn wound. Although the pliable characteristics that are possessed by groin flap are required to cover small cross-sectional diameter anatomic regions such as the wrist, its bulky appearance requires secondary reconstruction to thin the flap.

Keywords: electrical injury, groin flap, superficial circumflex iliac artery flap, upper extremity, reconstruction

BACKGROUND

Electrical burn injuries are associated with high morbidity and commonly occur in the upper extremities, particularly the wrists, forearms, and hands. The injury extends deeply into the underlying tissue causing tissue damage, thereby resulting in ischemia and subsequently, a high probability of extensive tissue necrosis.

The passage of an electrical current produces heat, leading to tissue damage. Because the current is transmitted along the path of least resistance through the body, it flows along neurovascular bundles. This causes extensive damage that involves the nerves, blood vessels, muscle, skin, tendon, and fat all the way through to the underlying bone. Bones retain the most body heat and possess the highest electrical resistance, particularly in the periosteal tissue such as that between two bones (e.g., tibia–fibula and radius–ulna). This is a contributing factor to delayed vascular occlusion and progressive tissue necrosis [1].

The cross-sectional diameter area of the involved body part affects its resistance and the magnitude of tissue damage. The wrist is an undersized cross-sectional area with tendon and bony structure areas that are highly resistant to heat and more severe damage. The peripheral nerve in minimal cross-sectional areas is located in close proximity to the bone and fibrous tissue. Therefore, an electrical injury is likely to lead to thrombosis of the perineural region, causing compression syndrome of the peripheral nerves. An experimental study conducted by Jia-ke et al., (2009) has shown irreversible vascular damage post burn injury via optical microscopy that was marked by the necrosis of the vascular walls and thrombosis along the areas of arterial endothelium destruction as well as pyknosis of vascular muscle with the presence of fibrinous exudates. Moreover, muscle viability progressively decreased between 30 min to 72 h after the injury, explaining the appearance of degeneration necrosis in certain muscle cells due to coagulation accompanied by myolysis [2].

Reconstructive surgery of electrical burn injuries is divided into primary and secondary stages. Vogt et al., [4] have described primary reconstruction as the surgical procedures performed in the early phases of the burn injury to decrease infection and improve wound healing. These procedures involve the debridement of devitalized tissue and wound closure using step-ladder reconstruction (from skin grafting to free flap). In contrast, secondary reconstruction is performed after the burn wounds have healed to enhance the function and aesthetics of the injured area, such as burn scar contracture release [3].

The timing of debridement remains controversial, with several studies both for and against performing treatment during the acute phase. Some literature suggests that primary reconstructive surgery should be performed within the first 3 weeks following an electrical burn injury because the passage of electric current causes vascular changes similar to ischemia–reperfusion injury, which disturbs the capillary blood flow and results in progressive tissue necrosis. Furthermore, several studies have hypothesized that less secondary reconstruction is required if there is an early coverage of exposed functionally important structures during the acute phase [4], [5].

The use of a distant flap, such as groin flap, may be considered as a substitution for free microvascular tissue transfer for the coverage of raw surfaces and important underlying tissue structures in the wrist. The groin flap is an axial fasciocutaneous flap vascularized by the superficial circumflex iliac artery. The artery is located parallel and approximately 2–3 cm distal to the inguinal ligament, able to cover an area of skin between 5 cm inferior and superior to the artery and approximately 5 cm above the anterior superior iliac spine. In cases of extensive coverage, a flap may be raised based upon the adjacent superficial epigastric artery [6]. We present a case series of electrical burn patients with wrist defects that were treated using an axial groin flap and propose this as an alternative method to free flap reconstruction.

CLINICAL QUESTION

According to a case series of electrical burn patients and evidence-based medicine, we posed the following clinical questions: 1) Does the two-stage surgical method affect the morbidity of electrical burn patients? and 2) Does the time of flap harvesting (delayed and non-delayed groin flap) affect flap vitality?

METHODS

Literature Review

We performed a database search of PubMed, ClinicalKey, and Google on May 30, 2019. The databases were searched using the Medical Subject Headings (MeSH) terms “Electric Burn Injuries,” “Groin Flap,” “Superficial Circumflex Iliac Flap,” “Upper Extremities,” and “Reconstruction” (Table 1). Inclusion criteria were English literature; adult populations with electrical burn injury in the upper extremities; the provision of preoperative, intraoperative, and follow-up postoperative data; and studies with distant flap intervention. We excluded studies concerning non-burn injury populations, the single intervention of local flap or free microvascular flap surgery, surgical intervention in areas other than the upper extremities, and pediatric populations. Following a full-text reading of the initial screening results, one study of a non-burn injury population was excluded because it was not comparable with the other screened studies (Figure 1).

Figure 1. Flow diagram of search strategy of literature performed on July 30, 2016.

Case Studies

We evaluated two case studies of electrical burn injury to the upper extremities with groin flap reconstruction.

RESULTS

Literature Review

The literature search identified three articles meeting our criteria for appraisal. There were one systematic review and two cohort studies, both valued as high-level evidence. Table 1 presents a critical appraisal of the articles. Handschin et al., study [6] included 68 patients with electrical injury, of which 40 suffered from low-voltage electrical burns. Mean burn wound size was $33\% \pm 22\%$ of the total body surface area, and 90% of cases involved the upper extremities. There were three cases wherein the groin flap was used to cover defects in the upper extremities. This study has suggested series debridement for the removal of visible necrotic tissue aggressively followed by immediate reconstruction. Microvascular thrombosis as an indication of flap failure appeared during the first 4 weeks. No information was provided regarding the type of groin flap performed in this study, and there was no history of bleeding reported in the patients undergoing the groin flap re-construction.

Case 1

A 32-year-old male presented at the emergency room with a chief complaint of electrical burn injury in both wrists and lower extremities that had occurred 2 weeks prior. There was no history of trauma, loss of consciousness, or fever. Fasciotomy and excisional debridement had already been performed twice at another hospital.

A raw surface sized 6.5×9.5 cm in the left wrist and 3×4.5 cm in first web space were noted. The underlying structure was difficult to identify due to eschar and necrotic tissue appearance in the wrist. The raw surface in the first webspace showed a subdermal wound bed with granulation tissue, and the proximal phalanx of the first digit was visible. The range of movement in the hands was limited due to pain and stiffness (Figure 2).

Radiographic findings revealed bilateral soft tissue swelling in the fascia antebrachii. There was subluxation of metacarpophalangeal digit 1 to the radial side and a closed incomplete fracture of the proximal phalanx digit 1 in the left hand. Destruction of the metadiaphysis/cortex of the distal right ulnar bone was detected on the anteromedial side with a lytic lesion in the epidiaphysis. There appeared to be periostitis in the metadiaphysis of the distal radius and ulnar joint (Figure 3).

The patient was diagnosed with a deep dermal electrical burn injury of $> 9\%$ of the total burn surface area with 2% raw surface. The debridement of nonvital structures, such as tendons (flexor system), muscle, and fat tissues, was performed 20 days after the burn injury (Figure 4). The ulnar artery was identified as compromised owing to thrombosis; however, adequate vascularization was sourced from the radial artery.

Figure 2. First clinical presentation of a 32-year-old male with bilateral electrical burn injury and raw wrist surfaces.

Figure 3. The radiographic findings reveal the appearance of osteomyelitis in the ulnar bone with marked periostitis in the distal region of the right radial bone (left). Subluxation of the left proximal phalange digit 1 to the radial side with an incomplete fracture of the proximal phalange of the left hand (right) is observed.

Figure 4. Post debridement (left) and post bilateral groin flap surgery (right).

Figure 5. Post groin flap surgery, the remaining raw surface was covered with a split-thickness skin graft.

Groin flap coverage of the bilateral raw surface was performed 5 days after debridement surgery (Figure 5). Due to the extensive circumference of the right wrist, the flap inset was delayed until blood flow to the distal portion was adequate. The right groin flap surgery was performed 10 days after the second procedure. The left side groin flap was separated at 21 days and the right-side groin flap at 11 days post debridement surgery. The evaluation of flap vitality was performed intraoperatively, and good vascularization of both flap pedicles was confirmed. A split-thickness skin graft was performed to achieve closure of the raw surface in the digit 1 of the left hand and the remaining raw surface proximal to the left groin flap. Owing to the instability of the distal radius–ulna joint, a transfixion wire was applied by an orthopedic surgeon.

Case 2

A 25-year-old male was diagnosed with a deep dermal electrical burn injury to his left hand that covered 2% of his total body surface area. The injury occurred 10 days prior to hospital admission. There was no history of trauma or loss of consciousness. A raw surface (8 × 4 cm) in the central palm of the hand extending from the proximal palmar crease to distal of the insertion of the flexor digitorum superficialis to digits 2–5 in the left hand was present. Another raw surface covered two-thirds of the circumference of the left wrist region. Exposure of underlying soft tissue (tendons and fascia) with granulation tissue was noted in the digits and wrist (Figure 6). The patient underwent debridement of nonvital structures between flexor zone 1 and 3, including flexor tendons, muscle, and fat tissues. Vascularization was found adequate from the radial artery, because of the non-vitality of the ulnar artery.

A left delayed groin flap closure of the raw wrist surface and a full-thickness skin graft was performed at day 13 post burn injury (Figure 7). An intraoperative evaluation of flap vitality showed good vascularization of the flap pedicle. At day 31, the patient underwent separation of the left delayed groin flap. During the postoperative evaluation, the flap showed no wound dehiscence or infection. However, a skin contraction due to healing of the full-thickness skin graft was observed.

Figure 6. First clinical presentation of a 25-year-old male with electrical burn injury covering two-thirds of the circumference of the left wrist and between the central palm of hand to the site of flexor digitorum superficialis insertion.

Figure 7. Left delayed groin flap closure at day 13 (left). Post separation of left groin flap (right).

DISCUSSION

Appraised articles are a systematic review and cohort studies, thus it valued as high-level evidences. Figure 2 shows critical appraisal of the articles. Handschin study [5] include 68 patients due to electrical injury and 40 burn patient has low voltage electric burn, with mean size of burn wound $33 \pm 22\%$ of TBSA with commonly involved upper extremities (90%). Total of three groin flap were used to cover defect in upper extremity. This study suggests series debridement for removal visible necrotic tissue aggressively followed by immediate reconstruction. Microvascular thrombosis as failure of flap appeared during the first 4 weeks. No information provided regarding type of groin flap performed in this study, however no history of bleeding reported in the groin flap patient.

Barillo et al., have described six cases of patients with severe hand burns. Three of them underwent primary reconstruction surgery using groin flap to cover the distal regions and fingers. This was followed by liposuction and defatting during the secondary reconstruction procedure at a later stage to decrease the bulkiness of the groin flap. The success rate varied from 50% to 100% flap viability. The Barillo study chose to perform immediate coverage using local, fascial, or fasciocutaneous flaps as well as distant flaps [6].

Jabir et al., have highlighted 12 cases of burn injury that included one patient with electrical burn in whom groin flap reconstruction was performed 4 days post injury. The failure rates were lowest when performed either during the immediate stage (within 5 days of injury) or within the intermediate stage (3 weeks after injury) and were highest when performed during the early stage (15–21 days after injury) [7]. Sabapathy et al., marked secondary reconstruction should be performed in about 6 to 8 weeks after the flap inset consideredema in the flap and induration at the suture line is settled, therefore flap becomes supple and the induration at the suture line reduced [8].

Flap failure was related to inadequate early debridement rather than the timing of reconstruction, and the timing did not appear to affect flap survival and outcome. Fasciocutaneous flaps are relatively thin, making them ideal for coverage in regions with exposed tendon and bony structures. This study revealed that the use of fasciocutaneous flaps to cover acute burn defects of hands demonstrated a low infection rate comparable with that of muscle flaps, despite the argumentation that a greater susceptibility to infection in comparison with muscle flaps would be caused by the comparatively inferior vascular plexus. No global evidence was found in the literature regarding whether the type of flap harvesting affected flap vitality.

Delayed groin flap has disadvantages as multi stage surgery procedure such as immobility of the hand, elbow, and shoulder that will lead to stiffness and edemaformation of the flap and upperextremity as a result of the dependent hand position [9,10]. Graf et al., study highlight decraesed mobility of joint in arm, increased with patient'sage [11], furthermore patient aged younger than 50 years hadless likely develop permaent problem with shoulder or elbow mobility. Evaluation post separation flap in mobility of shoulder and elbow joints compared to non injured side in both of patients showed no limitation in movement. Both patient were able to lift hand over 90 degrees and no complained to do daily activities.

Table 2. Evidence-based case report review

	Barillo (2001)	Handschin (2009)	Jabir(2014)
Design	Case series	Case series	Systematic review
Location	America	Zurich	Essex
Population	14-64 years adult population	A 53 yr male, chinese	A 52 yr female, chinese
Anatomical region	Upper extremities injury lower extremities injury	Upper extremity	Upper extremity Head and neck Lower extremity
Intervention	Groin flap as primary reconstruction	Groin flap as primary reconstruction procedure,	Groin flap with immediate (<5 days), early (5–22 days) and intermediate (23 days–6 weeks) post injury
Outcome	Two stage reconstruction surgery	Multiple stage surgery with serial debridement	Two stage reconstruction , primary reconstruction less than 5 days

CONCLUSION

The use of groin flap as distant pedicle flaps in cases of electrical burn injury provides an alternative when free flap reconstruction cannot be performed. In electrical burn injury, flap compromise is unrelated to the timing of the reconstruction surgery and caused by the pathophysiology of vascular occlusion and progressive tissue necrosis.

The ability to debride nonvital soft tissue without jeopardizing vital structures underlying the burn wound is critical. Pliable characteristics, such as those of groin flap, are required when covering small cross-sectional diameter anatomic regions such as the wrist. However, due to its bulky appearance, secondary reconstruction will be required to thin the groin flap.

Chapter 318

AUTOPSY OF AORTIC DISSECTION AFTER TEVAR INSTALLATION: A CASE REPORT

Yuli Budiningsih and Insil P. Hariyani*

Department of Forensic Medicine and Medicolegal Studies,
Cipto Mangunkusumo National Hospital,
Universitas Indonesia, Jakarta, Indonesia

ABSTRACT

Aortic dissection is a condition in which there is a tear in the aorta's tunica intima layer, leading to separation between the tunica intima and the tunica media, forming a false lumen. The incidence of aortic dissection is reportedly 5–30 cases per 1 million people per year. Thoracic endovascular aortic repair (TEVAR) is a recommended first-line therapy for patients with type B aortic dissection. The reported 30-day mortality rate and major complication rate with TEVAR are 5%–7% and 8%–10%, respectively. We report an autopsy of a 60-year-old German man diagnosed with Stanford type B (DeBakey type III) aortic dissection who underwent a debranching aorto-innominate-carotid graft (Y-graft) and TEVAR surgery. The external examination revealed postsurgical scars on the chest and left inguinal region along with injection marks on both upper extremities. The internal examination revealed blood inside the thorax; heart filled with blood and blood clots; cardiac enlargement; a constricted left coronary artery; an aortic wall laceration; separation of the tunica intima from the tunica media and adventitia throughout the ascending, descending, and abdominal aorta, forming a false lumen containing blood clots; atherosclerosis; and signs of damaged internal organs. There were some vascular Y-graft anastomoses from the ascending aorta to the end of the brachiocephalic artery and just before the branching of the left common carotid and left subclavian arteries. There was also an endovascular graft in the aortic lumen from the aortic arch to the thoracic aorta. Histopathological examination revealed an acute myocardial rupture, atherosclerosis in the left coronary artery, dissection of the aorta accompanied with erythrocyte infiltration in the aortic wall, and signs of internal organ congestion.

Keywords: aortic dissection; acute myocardial infarction; thoracic endovascular aortic repair.

INTRODUCTION

Acute aortic dissection is an age-related cardiovascular disease that has high morbidity and mortality due to complications. Autopsy studies confirm that acute aortic dissection is a life-threatening pathological state [1].

In recent years, 5–30 cases of aortic dissection per 1 million people have been reported annually [2,3]. Population-based studies have confirmed approximately three cases of aortic dissection per 100,000 people per year [1,4]. There are at least 7,000 cases per year in the United States [2].

Thoracic endovascular aortic repair (TEVAR) has recently emerged as the first-line approach for patients with type B aortic dissection. A 30-day mortality rate of 5%–17% and a major complication rate of 8%–10% after installation of TEVAR, have been reported [5].

CASE REPORT

On May 15th, 2017, the Department of Medical Forensic and Medicolegal Studies CMNH received a request from the German Embassy to perform a clinical autopsy on the body of a 60-year-old German man who had died after hospitalized at another hospital.

According to the medical resume, the man was diagnosed with Stanford type B (DeBakey type III) aortic dissection and had been treated for 15 days. His general physical examination revealed that his blood pressure was 190/96 mmHg, his pulse rate was 106 beats/minute, and his respiratory rate was 18 times/minute. The patient had undergone a Y-graft and TEVAR procedures.

The external examination took place on May 15th, 2017, at 16.45 Western Indonesian Time, while the body was still frozen. There were postoperative incision scars on the chest and left inguinal region, along with some needle tracks on both upper extremities.

An internal examination took place on May 15th, 2017, at 18.55 Western Indonesian Time. The examination revealed: 670 and 200 ml of blood inside the right and left thorax, respectively; an opened pericardial sac containing 130 ml of blood and 250 g of blood clots; heart enlargement; constriction of up to 75%–85% of the left coronary artery lumen; two irregular lacerations in the aortic arch (1 cm) and the descending aorta (2 cm), surrounded by infiltrated blood; separation of the tunica intima from the tunica media and adventitia throughout the ascending, descending, and abdominal aorta, forming a false lumen containing blood clots; atherosclerosis along the aortic arch to the abdominal aorta; and some signs of organ damage, such as pulmonary edema and aneurysms in the brain, digestive tract, liver, kidneys, and bladder. There were some vascular Y-graft anastomoses from the ascending aorta to the end of the brachiocephalic artery and just before the branching of the left common

carotid and the left subclavian artery. There was also an endovascular graft in the aortic lumen from the aortic arch to the thoracic aorta.

Histopathological examination revealed an acute myocardial rupture, erythrocyte infiltration, aortic dissection, atherosclerosis in the left coronary artery, and damage to the brain, lungs, liver, and lymph nodes.

DISCUSSION

Aortic dissection is a condition in which the tunica intima and the tunica media of the aorta separate and form a false lumen due to a laceration in the tunica intima. The International Registry of Acute Aortic Dissection reported the incidence of aortic dissection was highest during the sixth and seventh decades and mostly involved 62-year-old men. The incidence was more than twice as high in men than in women (68% vs. 32%). Likely, younger patients were also susceptible; the average age of male and female patients was 60 and 67 years, respectively. Seventy-five percent of patients, including the patient in our study, had a history of hypertension [4,6].

Three main systems are used to classify aortic dissection: DeBakey types I, II, and III; Stanford types A and B; and proximal and distal aortic dissection. The classifications are based on where the laceration in the tunica intima of the aortic wall and the false lumen are located. DeBakey type I is an aortic dissection in which the laceration is located in the ascending aorta and the false lumen is found along the aortic arch. In DeBakey type II, only the ascending aorta is involved. In DeBakey type III, the laceration is in the tunica intima in the descending aorta without involvement of the aortic arch and the ascending aorta. DeBakey type III has two subtypes. In subtype IIIa, the laceration is located only in the thoracic aorta; in subtype IIIb, the laceration also involves the abdominal aorta [1,7].

Stanford type A aortic dissection is located in the ascending aorta (DeBakey types I and II); Stanford type B aortic dissection is located in the descending aorta (DeBakey type III) [1,7].

A recent classification divides aortic dissections into five types, as shown in Figure 1.

The aortic wall is composed of three layers: the innermost tunica intima, the middle tunica media, and the outermost tunica adventitia. Acute aortic dissection occurs from the stress of systemic hypertension, which damages the aortic wall. Generally, this condition begins with a tear in the tunica intima, which then spreads to the tunica media along the aortic wall by pressure from the blood, resulting in a false lumen. The dissection can extend distally, proximally, and, eventually, throughout the aorta. In 90% of cases, a secondary tear in the intimomedia layer forms as the dissection extends, allowing blood to flow back into the true aortic lumen. While the primary laceration is often located in the thoracic aorta, the secondary tear is likely to appear below the descending aorta or in the abdominal aorta [8].

A cohort study by Bailey et al. [9] of 369 autopsies of aortic dissection cases over 16 years (1993–2008) suggested that atherosclerosis was a risk factor in 73% of fatal aortic dissections. The ulcerated atherosclerotic plaque might cause more damage to the tunica intima and lead to aortic dissection [9].

The recent INSTEAD-XL studies indicated that TEVAR could prolong the lives of aortic dissection patients by five years and delay progression of the Stanford type B aortic dissection, which often occurs as a complication of diseases such as uncontrolled hypertension, ruptured aorta, and end-organ ischemia. However, TEVAR's effectiveness for treating chronic complications of Stanford type B aortic dissection remains controversial [5].

Figure 3. Location of installation of TEVAR for Stanford type B [10] aortic dissection.

Our autopsy results showed that the frailty of the aortic wall due to atherosclerosis led to laceration in the ascending aorta, which resulted in blood flowing out to the cardiac and thorax. Blood inside the cardiac could promote pericardial tamponade and disrupt cardiac movements. We also found a laceration in the tunica intima of the descending aorta and dissection along the descending aorta to the bifurcation of the iliac arteries. We detected a TEVAR graft in the aorta and blood clots inside the false lumen.

Figure 4. (a) Laceration in the ascending aorta; (b) aortic dissection; (c) TEVAR graft.

Our autopsy also revealed a lumen constriction of up to 75%–85% due to a thickened left coronary artery and an acute myocardial infarction image in the myocardium.

Atherosclerosis of the coronary arteries is a potentially fatal disease. This disease reportedly causes at least 25%–40% of deaths. One interesting finding of our autopsy is that atherosclerotic constriction of the left coronary artery occurred in more than 75% of the lumen. This finding is contrary to most atherosclerotic constriction cases where the constriction occurred in less than 75% of the lumen. Necrotic myocardium may occur if the lumen is constricted by 20% or less, followed by ischemia in the artery distribution area [6, 11].

Figure 7. Narrowing of the left coronary artery lumen opening.

Figure 8. Histopathological image of the left coronary artery.

Figure 10. Myocardial infarction.

Figure 11. Histopathological image of the myocardium showing myocardial rupture.

This 60-year-old German man appeared to die from natural causes. The external examination revealed several postoperative wounds and signs of damage. The internal examination revealed a TEVAR-corrected Stanford type B (DeBakey type III) aortic dissection. The autopsy also revealed a laceration in the ascending aorta that caused bleeding in the thorax and cardiac. The autopsy confirmed constriction of the left coronary artery lumen by 75%–85% due to atherosclerosis and myocardial infarction. We observed blood and blood clots inside the cardiac that caused cardiac tamponade. The histopathological images confirmed our internal examination findings of myocardial infarction, left coronary artery atherosclerosis, aortic dissection with erythrocyte infiltration, and signs of damage to the brain, lungs, and liver. In this case, cardiac tamponade caused myocardial infarction, which disrupted cardiac movements and led to death.

ABSTRACT

Meningioma is the most common type of benign intracranial tumor. The occurrence of extracranial meningioma is rare, accounting for only 2% of all meningiomas. There are two types of extracranial meningioma: primary and secondary. Primary extracranial meningioma grows extracranially without any connection to intracranial lesions, whereas secondary extracranial meningioma is an intracranial meningioma that extends extracranially. Herein, we report the case of a 45-year-old female patient with secondary extracranial sinonasal meningioma who presented with intermittent headache and unilateral proptosis due to olfactory groove meningioma that expanded to the right ethmoid sinus. Gross tumor resection was achieved in this case.

Keywords: extracranial meningioma, sinonasal meningioma, secondary extracranial meningioma, transitional meningioma

* Corresponding Author's Email: renindra03@yahoo.com.

INTRODUCTION

Meningiomas are originated from meningeal coverings and arachnoid cap cells found in the arachnoid villi at cranial vault and base, as well as in the spinal region [1]. Hitherto, various registries from countries worldwide have shown an increase in meningioma incidence [2-5]. Although studies on meningiomas in general are abound, particular studies on extracranial meningiomas are lacking.

Extracranial, or ectopic, meningioma accounts for approximately 2% of all meningiomas [6-8]. There are two types of extracranial meningioma: primary and secondary. While the former has no connection to intracranial lesions, the latter is a direct extension of intracranial lesions to extracranial sites [6-8]. Due to the rare occurrence of secondary extracranial meningioma, its diagnosis and management requires a thorough and cautious approach. In this report, we present the rare case of a secondary extracranial meningioma in the sinonasal area that originated from the olfactory groove area.

CASE REPORT

A 45-year-old female patient presented with a history of progressive intermittent headache since 3 years, followed by progressive protrusion of the right eye since 2 years ago (see Figure 1). The patient had no complains of blurred vision, visual field deficit, double vision, epistaxis, nasal obstruction, rhinorrhea, and smell disorder. Upon neurologic examination, proptosis was identified with a slight decrease in visual acuity in the right eye (6/8.5 on the Snellen chart), unilateral ophthalmoparesis, unilateral anosmia, and bilateral papilledema. No other abnormalities were found. Contrast-enhanced brain computed tomography (CT) revealed a homogenous hyperdense lesion in the bilateral frontal bone with expansion to the right ethmoidal sinus (see Figure 2). Further imaging with contrast-enhanced

Figure 1. Anterior and lateral view of the patient's face showing obvious protrusion in the right eye.

T1-weighted magnetic resonance imaging (MRI) revealed homogenous hyper-intense enhancement of the lesion (see Figure 3). The patient underwent craniotomy for removal of the tumor, which had areddish-white macroscopic appearance, firm consistency, and could easily bleed (see Figure 4). Histopathologic examinations revealed a grade 1 meningioma

(mixed meningioma, also referred to as transitional meningioma) based on the World Health Organization (WHO) classification (9). The case was uneventful, and the patient was discharged 1 week after surgery. Post-operative CT exhibited gross total tumor removal (see Figure 5).

Figure 2. Axial, coronal, and sagittal views of contrast-enhanced computed tomography scan revealed a bilateral frontal mass that expands to the right ethmoidal sinus.

Figure 3. Contrast-enhanced T1-weighted magnetic resonance imaging revealed a homogenous hyperintense lesion in the bilateral frontal lobes extending to the right ethmoidal sinus.

Figure 4. Intraoperative macroscopic view of the lesion: reddish-white appearance, firm, and bleeds easily.

Figure 5. Postoperative axial, coronal, and sagittal computed tomography scan images.

DISCUSSION

Meningioma is the most common benign intracranial tumor, which accounts for 13% – 30% of primary intracranial tumors [6, 7]. Genetic factors, such as neurofibromatosis type-2 and multiple endocrine neoplasia type-1, increase the likelihood of meningiomas [11, 12]. Other risk factors for meningioma are ionized radiation exposure, hormonal exposure, brain trauma, and history of breast cancer. Although there is no evidence that hormonal exposure increases the risk of developing meningioma significantly, its incidence is more prevalent in

women than in men (2:1), particularly for grade I meningioma. Meanwhile, for grade II and III meningiomas, the incidence is higher in men than in women (1.2:1) [10-12].

There are two types of meningioma: intracranial and extracranial. Intracranial meningioma is covered by dura mater, whereas extracranial meningioma is not covered by dura mater. The extracranial subtype accounts for approximately 2% of all meningiomas [6-9]. Extracranial meningioma can be classified into two types: primary and secondary. Meningiomas that arise extracranially without any association with an intracranial mass are referred to as primary extracranial meningiomas. Secondary extracranial meningiomas are extensions from intracranial disease. The tumor may enter the orbit and nasal cavity through preformed bony pathways, surgical defects, or foramina of the skull base [6-8]. Hoyer (1960) has developed a classification system of extracranial meningiomas (Table 1) [14]. Another classification system was established by Atherio et al., which divided extracranial meningioma into four groups [15]: (i) primary extracranial meningiomas extending from the skull, (ii) extracranial meningioma arising from the arachnoid cell rests of cranial nerve sheaths, (iii) meningiomas with no obvious connection with the foramina or cranial nerves, and (iv) metastasis of malignant intracranial meningiomas.

Table 1. Hoyer classification of extracranial meningiomas [14]

Primary	Secondary
Extracranial extension of a meningioma arising from the neural foramina	Extracranial extension of the meningioma from the intracranial meningioma
Ectopic, without any connection to the neural foramina or intracranial structure	Extracranial extension from metastasis of intracranial meningioma

Several theories regarding the mechanism of primary extracranial meningioma have been proposed, which were as follows: extradural entrapment of arachnoid cells during embryogenesis, ectopic migration of arachnoid cells in the development of peripheral nerves, and metaplasia of mature peripheral nerve sheath or progenitor cells [8]. The most common site for extending intracranial meningioma is the orbit, and other sites include the nasopharynx, scalp, sinuses (frontal sinus, maxillary sinuses, ethmoidal sinus, and sphenoid sinuses), parapharyngeal region, and parotid gland [8]. Although meningiomas have the capability to expand extracranially, they rarely invade the brain [8].

Cautious and systematic anamnesis; physical examinations; and imaging histopathological, and immunohistochemical studies must be conducted to diagnose meningiomas accurately. Anamnesis and physical examinations can help identify signs and symptoms with regard to tumor location. In our patient, intermittent progressive headache, unilateral proptosis, and anosmia were identified. Non-contrast-enhanced CT can reveal hyper- or isodense lesion (15% – 20% cases can present with reveal calcification), which enhances homogeneously. T1-weighted MRI can reveal iso- to hypo-intense lesions, which are homogeneously enhanced with the administration of gadolinium, whereas T2-weighted MRI usually reveal iso- to hyper-intense lesions. Peritumoural edema is observed in 60% of cases [13]. Histopathology studies aim to classify meningiomas according to WHO grading and to determine the most appropriate treatment. Immunohistochemical studies have used vimentin and epithelial membrane antigens for the diagnosis of meningiomas [16]. However, both were not examined in this study.

Gross total resection remains the standard treatment for all meningiomas [13], although this may not be the case for the management of skull base meningiomas. Nevertheless, surgeons should aim to achieve Simpson grade I resection during the first surgery.

CONCLUSION

This study reported a case of secondary extracranial sinonasal meningioma. Physical examinations; cautious and systematic anamnesis; and imaging, histopathological, and immunohistochemical studies must be performed to diagnose this rare type of meningioma accurately. Gross total resection of the tumor, dural attachment, and abnormal bone should be performed to achieve low recurrence, although tumor location may be used as basis for the extent of resection.

ABSTRACT

Currently, there has been an increase in the incidence of acute pancreatitis worldwide. Despite the improvements in access to care, imaging, and interventional techniques, acute pancreatitis continues to be associated with significant morbidity and mortality. Pain control is an important part of supportive management for patients with acute pancreatitis. A 26-year-old woman presented to our emergency department with a distended abdomen and excruciating pain in the upper abdomen. She was diagnosed with acute pancreatitis. She developed acute respiratory distress; thus, she was intubated and admitted to the intensive care unit. Her upper abdominal pain gradually intensified, causing worsening of acute respiratory distress syndrome. Opioids did not considerably relieve her pain; moreover, their side effects worsened acute pancreatitis. Moreover, thoracic epidural analgesia at the T7–T8 interspace was considered for pain management. After the administration of epidural analgesia, pain substantially improved, abdominal distention markedly reduced, amylase and lipase levels gradually returned to normal, and she was eventually weaned off the ventilator. Epidural analgesia is one of the important pain management modalities, and it stops severe acute pancreatitis development by improving splanchnic and pancreatic perfusion, resulting in decreased liver damage and inflammatory responses.

INTRODUCTION

The most severe forms of acute pancreatitis (AP) are associated with high morbidity and mortality. AP has an overall mortality rate of approximately 5%, and most patients with severe AP require intubation and mechanical ventilation [1, 2]. Although the pathophysiologic cascade of its development and progress is poorly understood, microcirculatory disturbances are considered important factors [3]. Different therapeutic interventions for improving pancreatic microcirculation have been evaluated in recent years. The current treatment for AP involves supportive medical therapy, which is sometimes associated with endoscopic procedures and/or surgical interventions. Therapeutic efforts are aimed at saving injured tissue from infarction and necrosis by improving microcirculatory perfusion and oxygen supply [2, 3].

Pain control is an important part of supportive management in patients with AP. Therefore, in the absence of any patient-specific contraindications, a multimodal analgesic regimen is recommended, including narcotics, nonsteroidal anti-inflammatory drugs (NSAIDs), and acetaminophen [4, 5]. The optimal recommendation is adherence to the most current acute pain management guidelines in the perioperative setting. However, all patients with AP should receive some form of analgesia in the first 24 hours of hospitalization to avoid compromise of quality of life [6, 7, 8]. Recently, increasing evidence from preclinical and clinical studies has supported the beneficial effects of thoracic epidural analgesia (TEA) in AP, such as improved gut barrier function and splanchnic, pancreatic, and renal perfusion; decreased liver damage and inflammatory responses; and reduced mortality [1]. Here, we present a report on a critically ill patient with AP who was successfully treated with TEA.

CASE REPORT

A 26-year-old woman was referred to our emergency department with excruciating pain in the upper abdomen and a distended abdomen. Her clinical findings supported a diagnosis of AP. She developed acute respiratory distress syndrome (ARDS) and was intubated. She was then admitted to the intensive care unit (ICU) for further management.

Figure 1. Amylase and lipase levels and pain intensity according to the visual analogue scale during treatment before and after thoracic epidural analgesia in our patient.

Her upper abdominal pain gradually intensified, causing worsening of ARDS and ventilator-patient asynchrony, and therefore, difficulty in ventilator weaning. Several AP laboratory markers, such as amylase and lipase, increased (Figure 1).

Opioids did not significantly relieve her pain; moreover, the side effects worsened her AP. TEA was then considered for pain management, in addition to the prevention of the development of severe AP owing to redistribution of splanchnic blood flow to non-perfused pancreatic regions.

DISCUSSION

The most common and significant complain associated with the diagnosis of AP is pain, and therefore, adequate analgesia represents an important part of the treatment approach [2]. Sensory information from the pancreas is transmitted to the central nervous system via both vagal and spinal pathways. Cell bodies of the spinal afferent pancreatic neurons are located in the T6–L2 dorsal root ganglia, and their axons traverse the splanchnic nerves and celiac plexus before they enter the pancreas [9]. Sensory nerves are responsible for the regulation of pancreatic blood flow, and stimulation of the sensory nerves could produce hyperemia in the pancreatic microcirculation. Previous studies have shown that the protective effects of the sensory nerves on necrotizing pancreatitis are manifested by decreases in plasma amylase and lipase activities, a reduction in the plasma IL-1 level, and an increase in pancreatic DNA synthesis [10, 11].

AP treatment depends mainly on the severity of progression, but almost all cases will require supportive treatments, such as analgesics. Effective treatments of pain in AP range from the administration of simple analgesic drugs, which might be sufficient for patients with mild AP, to the administration of potent opioids, administration of high doses of antibiotics for infected pancreatic necrosis, and even surgical or interventional procedures for cases of severe AP. The World Health Organization analgesic ladder (Figure 2), which includes the use of NSAIDs or their combination with highly potent opioid analgesics in an escalating regime, for the management of abdominal pain mentions the use of interventional strategies depending on the occurrence of AP-related complications [12]. Opioids, such as morphine and its derivatives, are commonly used; however, there is no concrete evidence for their effectiveness and safety. They might hide disease resolution and might increase pain by causing spasms [13]. Besides parenteral pain control, epidural analgesia can be used as an alternative treatment. A previous experimental prospective study assessed the effects of sympathetic block by thoracic epidural anesthesia and found enhanced microcirculatory perfusion and end-organ perfusion and improved survival compared with controls in animal experiments [3]. However, these positive experimental results cannot be automatically transposed to humans since the investigation on regarding the splanchnic perfusion in human have not been cleared [2, 14]. Nevertheless, as the risk of significant morbidity with severe AP is high, it might be reasonable to accept a low rate of TEA complications if a major reduction in mortality is confirmed [14].

TEA can be considered for patients with severe and critical AP who require high doses of opioids for an extended period. Although it has been reported that analgesics could be administered transdermally or rectally, no RCTs have compared the different routes of

administration of the same analgesic in patients with AP [15]. The use of TEA in the acute clinical setting of severe AP and sepsis remains a fascinating area of research. Reliable non-invasive measures of splanchnic perfusion need to be developed for further evaluation of the effects of TEA on basic human physiological parameters and for direct randomized trials in critically ill patients [14].

Figure 2. The modified World Health Organization analgesia ladder according to Vargas-Schaffer [12].

In the present case, epidural analgesia had benefits for AP. This approach is safe and titratable and has minimum side effects compared to other modalities in such a patient. TEA installation at level T5 to T10 was proven to be appropriate and cover the affected dermatome, this was shown in significant reduce in VAS, thus the patient became more comfortable, marked by synchronized breathing with ventilator. It also prevented further progression of the disease by improving splanchnic and pancreatic perfusion. Shortly after the epidural regimen, abdominal distention markedly reduced, amylase and lipase levels gradually returned to normal, and the patient was successfully weaned off from the ventilator.

CONCLUSION

Epidural anesthesia has a major role in AP management. It is one of the important pain management modalities, and it stops severe AP development by improving splanchnic and pancreatic perfusion, resulting in decreased liver damage and inflammatory responses.

ABSTRACT

ABO-incompatible kidney transplantation (ABOi-KT) is a strategy to overcome the shortage of organ donors. It is considered a high-risk option because of potential antibody-mediated rejection (AMR); however, it results in improved outcomes because of the use of more potent immunosuppressants in combination with splenectomy and therapeutic plasma exchange (TPE). We reported a case of a 54-year-old male O-blood type recipient who received an A-blood type living donor kidney. The desensitization protocol consisted of a combination of three sessions of TPE with immunosuppressants administered prior to transplantation. The anti-A antibody IgM-IgG titers could be reduced and maintained at a range of 1:32–1:4. Additionally, the fibrinogen level was 245 mg/dl prior to transplantation without any fresh frozen plasma (FFP) replacement. There was massive postoperative bleeding due to the low fibrinogen level. The patient received cryoprecipitates and intravenous tranexamic acid. The bleeding gradually stopped, and the graft function was good. The patient was discharged from the hospital on day-7 post-transplantation. Preoperative TPE was the primary therapy for ABOi-KT in this patient. Only three sessions were performed, but it caused hypofibrinogenemia and

* Corresponding Author's Email: ditaaditiaa@gmail.com.

postoperative bleeding. Coagulation factor monitoring and blood component therapy were essential to prevent these complications.

Keywords: ABO-incompatibility, kidney donor, therapeutic plasma exchange, hypofibrinogenemia

INTRODUCTION

Kidney transplantation is the treatment of choice for patients with end-stage renal disease (ESRD); however, there is currently a long waiting list for organ donors. Blood type-incompatible transplantation is one of the alternatives to overcome the shortage of organ donors [1]. ABO-incompatible kidney transplantation (ABOi-KT) is considered a high-risk option because of antibody-mediated rejection (AMR) and declining graft survival. Desensitization protocols for ABOi-KT are designed to improve this outcome. These protocols consist of splenectomy and a combination of immunosuppressants, such as high-dose intravenous immunoglobulin, anti-CD20 monoclonal antibody agents, and therapeutic plasma exchange (TPE) [2]. A splenectomy is performed to remove the major B-cell reservoir and prevent AMR; however, its effect on the immune system is irreversible, and it has a higher risk of infections. In 2004, rituximab, the anti-CD20 monoclonal antibody, was introduced and gradually replaced splenectomy. Rituximab binds to CD20 and produces along-acting B-cell suppression effect by inducing complement cytotoxicity, antibody cytotoxicity, and apoptosis on immature and mature B-cells, except for memory B-cells and plasma cells [3]. Preoperative antibody removal is achieved by plasma exchange or plasmapheresis as a part of desensitization for ABOi-KT. TPE removes high-molecular-weight antibodies from the plasma by using an automated blood cell separator to filter the plasma and separate the immunoglobulins to be discarded. TPE can remove 60%–70% of antibodies per session and is more efficient than classic plasmapheresis, which separates immunoglobulins by centrifugation and removes only 40%–50% of antibodies per session. This method requires a femoral, subclavian, or internal jugular double-lumen catheter insertion to ensure adequate blood flow during the procedure. TPE can be performed prior to or post operation, or both. Most cases require three to seven sessions, depending on the initial or elevated antibody titers post transplantation. Each session removes 1–1.5 times the plasma volume (calculated based on hematocrit and predicted body weight), which is replaced by 5% albumin, fresh frozen plasma (FFP), or both. Albumin is a preferable replacement fluid because it has a lower risk of hypersensitivity and infection transmission compared with FFP. However, TPE has a higher risk of bleeding due to the removal of coagulation factors; therefore, FFP is usually reserved to correct coagulation factor and bleeding complications [4].

CASE REPORT

A 54-year-old male was scheduled to undergo a living donor kidney transplant. His blood type was O rhesus +, and the donor blood type was A rhesus +. The recipient had

hypertension since 2008. He was diagnosed with end-stage chronic kidney disease in 2015 and underwent hemodialysis for four months prior to transplantation. A physical examination revealed a good general appearance, with a body mass index (BMI) of 24.9 kg/m2 and grade I hypertension (BP 140 – 150/70 – 80 mmHg), which was treated with amlodipine 1 × 10 mg, clonidine 4 × 0.15 mg, bisoprolol 1 × 5 mg, and valsartan 1 × 160 mg. The donor-recipient complement-dependent cytotoxicity crossmatching result showed 10% – 20% lysis (negative result). A desensitization protocol was initiated eight days prior to transplantation. The protocol consisted of immunosuppressants (tacrolimus 10 mg/day PO, rituximab 500 mg/m2 IV, mycophenolate mofetil 1,000 mg/day PO, and methylprednisolone 24 mg PO), and TPE was performed with the Prismaflex system (Gambro, Sweden), only three times every other day, five days prior to transplantation. The hemoglobin level of the patient was 6.1 g/dl, and he received a transfusion of leucodepleted packed red cells (PRCs) before the first TPE was conducted. One and a half times the plasma volume was removed, and 5% albumin with anticoagulant heparin was used as the replacement in every session. A timeline of the protocol is explained in Figure 1.

Figure 1. The ABOi-KT desensitization protocol used for this patient. TPE, therapeutic plasma exchange; HD, hemodialysis; KT, kidney transplantation.

INVESTIGATIONS

The initial anti-A antibody IgM-IgG titers were 1:256 – 1:4, which were reduced to 1:64 – 1:4 and 1:32 – 1:4 in response to three sessions of TPE. The prothrombin time (PT), activated prothrombin time (APTT), and fibrinogen levels were within normal limits without any replacement of fresh frozen plasma (FFP) or cryoprecipitate during the TPE sessions prior to surgery. Basiliximab (20 mg) was administered in the morning prior to transplantation. The transplantation procedure took 3 hours and 45 minutes to complete, with a primary warm ischemic time of 2 minutes and 27 seconds, a cold ischemic time of 23 minutes and 12 seconds, and a secondary warm ischemic time of 30 minutes and 24 seconds. The recipient’s urine was produced on the 40th minute after reperfusion. During the surgical procedure, the patient received 1,250 cc of IV solution; conversely, the total output was 850 cc, with 250 cc coming from blood loss during the procedure and 600 cc from urine output. The patient had significant bleeding from the wound and 450 cc drainage production of

serous hemorrhage within one hour postoperatively. The hemoglobin level decreased to 6.1 gr/dl, and the fibrinogen level was low (30.2 mg/dl). The graph of antibody titers, creatinine level and fibrinogen level dynamics before, during and after TPE, and after transplantation procedure was explained in Figure 2.

Figure 2. ABO-IgM-IgG antibody titers, creatinine level, and fibrinogen level before and after TPE, during TPE, and after transplantation. TPE, therapeutic plasma exchange; IgM-G, immunoglobulin M-G.

TREATMENT

The patient had significant bleeding from the wound and a drainage production of 450 cc serous hemorrhage within one hour post transplantation. His hemoglobin level decreased to 6.1 gr/dl, and his fibrinogen level was low (30.2 mg/dl). Therefore, 500 ml of leucodepleted PRCs and 10 units of cryoprecipitate were administered along with tranexamic acid, which was given as a 1 gram bolus followed by the infusion of 3 grams over 24-hour. The total blood loss after the operation was approximately 840 ml in 17 hours, and drainage production decreased over the next 24 hours. His fibrinogen level increased to 190 mg/dl, and his hemoglobin level was 7.3 gr/dl. The general condition of the patient was stable.

OUTCOME AND FOLLOW-UP

The patient was followed up for seven days post transplantation, and the general condition of the patient was stable. His fibrinogen level increased to 173 mg/dl on postoperation day-1 and to 190 mg/dl on postoperation day-2. His urine output was greater than 1 ml/kgBW/h with serum creatinine level and estimated glomerular rate (eGFR) showed

improvement postoperatively. There was no sign of rejection or transfusion-related complications, and the patient was discharged from the hospital on the 8th day post-transplantation.

DISCUSSION

The principle of the immunosuppressive strategy in ABOi-KT is a desensitization strategy that consists of antibody removal or depletion, induction, and maintenance of immunosuppression agents. Alexandre et al. successfully attenuated the immunologic reaction and prevented hyperacute rejection by initiating a desensitization protocol that involves preoperative splenectomy and plasmapheresis. However, since 2004, splenectomy has rarely been performed because of the elimination effect on the immune system and the increased risk of infection [5]. Rituximab has become an alternative to splenectomy because it reduces B-cell production and attenuates the T-cell response within 1 to 3 days after induction; these responses persist for up to two years [6]. TPE is performed prior to transplantation to maintain the anti-A antibody titer between 1:4 and 1:32 in the beginning of transplantation. Several studies have shown that if the titer is less than 1:32, AMR is unlikely to occur [7]. Two studies also reported that the level of anti-ABO IgG antibodies was a more significant independent risk factor of AMR than IgM [8, 9]. After receiving only three sessions of TPE prior to the operation, this patient reached the following preoperative levels: IgM anti-A 1:32 and IgG anti-A 1:4. Since the prognostic value of the baseline anti-ABO titer is not yet established, it was considered safe to proceed with the transplantation for this patient.

TPE with one plasma volume can remove 40% – 50% of the antibodies per session because of the movement of extravascular constituents to the intravascular compartment and the resynthesizing of antibodies [10]. We performed TPE with 1.5 plasma volumes to increase the efficiency of antibody removal per session, which is calculated by the following formula:

$$(100 - \text{Hematocrit})\% \times (\text{KgBW} \times 70) \times 1.5 \text{ ml}$$

TPE removes anti-ABO antibodies along with plasma proteins, such as albumin, coagulation factors, and important immunoglobulins. It is replaced by 5% albumin solution or ABO group FFP during the sessions. Albumin is preferred to FFP because it has a lower risk of infection, hypersensitivity reaction, and reduced risk of ABO-related rejection. However, TPE increases the risk of bleeding, particularly during and after operation because of depleted coagulation factors other than antibodies. We replaced the 1.5 plasma volumes with only 5% albumin in each TPE session. PT, APTT, and fibrinogen levels were measured after each TPE session. FFP or cryoprecipitate were not used during TPE because the PT and APTT results were normal and the fibrinogen level was always above 100 mg/dl until two days prior to the operation. The patient suffered from bleeding complications after the operation. The fibrinogen level was very low, whereas the PT and APTT levels were still within normal limits. After administering 10 units of cryoprecipitate and tranexamic acid infusions, the bleeding gradually stopped, and the fibrinogen level increased. We closely monitored the

bleeding events for 72 hours since the effects of hypofibrinogenemia may persist for up to three days, although the fibrinogen biosynthesis rate may increase two- to four-fold per day during the acute phase. TPE may reduce fibrinogen levels by 64% – 80% depending on the individual's condition and extensive rate of TPE. Immunoabsorption is another technique that selectively removes immunoglobulins from separated plasma through high-affinity absorbers and only reduces the fibrinogen level by 20% – 35%. However, our center had no experience using this technique. The incidence of bleeding after the TPE was relatively low (0.06% – 2.3%). Hypofibrinogenemia contributes to bleeding complications in patients using anticoagulants who undergo invasive procedures or surgery [11].

Using FFP in addition to 5% albumin as a replacement during TPE can decrease the reduction in fibrinogen levels. However, the prevention of hypofibrinogenemia by FFP administration during TPE is currently not recommended. The FFP replacement is reserved for patients who are already hemostatically compromised or have a high risk of bleeding. This is because of the risk of adverse events, such as hypersensitivity reaction, transfusion-related circulatory overload, and transfusion-related acute lung injury. Cryoprecipitate has similar disadvantages of FFP, but it contains higher concentrations of fibrinogen, factor VIII, and von Willebrand factor with a lower infusion volume. We administered cryoprecipitate combined with a tranexamic acid infusion when the patient presented with significant bleeding and low fibrinogen levels (below 100 mg/dl). Cryoprecipitate and tranexamic acid administration can improve fibrin formation and platelet aggregation. This present combination prevents massive transfusions and is associated with an improved survival rate in trauma-related bleeding [11-13].

CONCLUSION

TPE reduces the fibrinogen level, and FFP or cryoprecipitate may be administered when there is significant bleeding along with low fibrinogen levels or prolonged APTT to reduce the antibody-related risk of transfusion. Pre- and post-TPE fibrinogen levels should be closely monitored in patients who undergo invasive procedures due to the potentially tremendous decrease in fibrinogen levels, which contributes to bleeding complications. In the present patient, the combination of cryoprecipitate transfusion and tranexamic acid administration replenished the fibrinogen level and overcame the bleeding complications with an acceptable amount of blood products.

SYMMETRICAL BILATERAL KEYSTONE PERFORATOR ISLAND FLAPS FOR VULVAR RECONSTRUCTION AFTER ONCOLOGICAL RESECTION: A CASE REPORT

Indri Aulia^{*}, Chaula Luthfia Sukasah and Eva Chintia Yessica

External Genitalia Section, Plastic Reconstructive and Aesthetic Surgery Division,
Department of Surgery, Universitas Indonesia, Dr. Cipto Mangunkusumo Hospital,
Jakarta, Indonesia

ABSTRACT

The vulvoperineal region is key to the urinary and reproductive systems and closely related to the gastrointestinal system. Most vulvar defects are resulted from tumor ablation. Therefore, the reconstruction after oncological resection remains challenging as it aims to restore adequate function with an ideal aesthetic result. We report a case of a 46-year-old female with extramammary Paget's disease of the vulva. She underwent oncological excision for vulvar reconstruction. Keystone perforator island flaps were performed in this patient and it demonstrated a symmetrical bilateral result of vulva subunits. The patient was satisfied with the vulva appearance and no limitations in daily activities was reported. The use of keystone perforator island flaps is a superior option for vulva reconstruction to achieve a symmetrical outcome.

Keywords: Keystone flap, vulvar reconstruction, oncological resection

INTRODUCTION

The vulvoperineal region is key to the urinary, reproductive, and gastrointestinal systems. Most vulvar defects are caused by oncological resection [1]. However, the extent of surgery

^{*} Corresponding Author's Email: drindriaulia@gmail.com.

varies from limited resection of pre-cancerous lesions to more extensive, bilateral radical vulvectomy for advanced cancer.

The reconstruction of vulvar defects after oncological resection remains challenging due to the high risk of postoperative infection because the area is easily contaminated and damp [2-4]. Poor wound healing and dehiscence might be also resulted from tension and traction upon movement of the affected region [5, 6]. Therefore, the reconstruction target is to restore adequate function and an ideal aesthetic appearance with minimal postoperative complications.

Various techniques have been developed for the reconstruction of vulvar defects, including the use of pedicled flaps [7-11]. However, this procedure might result in bulky flaps and asymmetrical coverage and could be insufficient for achieving appropriate aesthetic and functional results [12].

CASE

Patients with malignancy, especially vulvar malignancy, are treated with interdisciplinary management. In June 2017, a 46-year-old woman was diagnosed with extramammary Paget's disease of the vulva at the Gynecology Department of Dr. Cipto Mangunkusumo Hospital (Jakarta, Indonesia) and underwent an excision procedure conducted by an oncogynecologist. She was consulted to the Department of Plastic Surgery for further reconstruction of the vulva, which was performed using two keystone perforator island flaps from the lateral sides of the defect.

Figure 1. A: Vulvar defects of the patient with extramammary Paget's disease. B: Design of keystone perforator island flap. C: Immediate postoperative appearance. D–F: appearance of the flap 9 months after reconstruction.

DISCUSSION

Extramammary Paget's disease is an uncommon skin cancer involving genital, anal and perineum area [13]. It initially manifests as rash, scales and crusts that progresses into a wider and more severe lesion. Thus, a reconstructive surgery is necessary following excision of the primary lesion. In this case, we decided to perform keystone perforator island flaps to close the defect.

The keystone perforator island flaps survived in the patient with no complications of wound dehiscence or postoperative infection. In addition, there was no evidence of recurrence during nine months after the surgery. The vulvar region appeared to be symmetrical. Subjectively, the patient was satisfied with the appearance of the reconstructed vulva and had no complaints with urination, sexual activity, or daily activities. However, after the 9-month follow-up, the patient requested a minor revision to flatten the inferior part of the flap, which was slightly bulky. As with the first reconstruction, there were no complications with the revision procedure.

Figure 2. A: Keystone perforator island flap at 9 months after surgery. B: Appearance after revision surgery.

The use of keystone perforator island flaps resulted in symmetrical bilateral outcomes of the vulvar subunits. A 1:1 defect and flap ratio was applied to accurately place the midline. The initial incision and the final sutured lines were placed at the borders of the subunits to create a disguising scar.

CONCLUSION

Based on our experience, we found that keystone perforator island flaps has a lot of advantages for patients with vulvar defects. It has a simple design, symmetrical vulvar subunits results and it is applicable for defects in any part of the vulva. The appearance of the normal vulva is obtained by resurfacing the defect with tissue alike and applying it tightly as a young women's vulva. Minor revision is an additional procedure based on subjective desires in providing the daily needs and self-confidence. In conclusion, we believe that the use of keystone perforator island flaps is a good alternative for achieving functional and ideal aesthetic results of vulvar reconstruction.

Chapter 323

RECONSTRUCTION OF AURICLE AFTER WIDE EXCISION OF GIANT MULTIPLE CONGENITAL MELANOCYTIC NEVUS OF THE EAR: A RARE CASE REPORT

Dini Widiarni Widodo* and Ferucha Moulanda

Department of Otorhinolaryngology Head and Neck, Faculty of Medicine,
Universitas Indonesia - CiptoMangunkusumo General Hospital, Jakarta, Indonesia

ABSTRACT

Congenital melanocytic nevus (CMN) is a benign proliferation of melanocytes that appears at birth or within weeks of life. The condition occurs in 1% – 2% of newborns, with a 2% – 42% and 6% – 14% risk of transforming into malignancy or developing into multiple myeloma. The occurrence of CMN involving the auricular area is uncommon. Although excision of the nevus is the treatment of choice, this procedure is challenging. A wide area of CMN requires extensive excision coupled with a reconstructive procedure. In this article, we present a case of giant CMN in a 6-year-old female with giant pigmented nevi appearing after birth in all parts of her body, particularly the right facial, auricular, post auricular, mastoid, and neck areas. The diagnosis was reached based on the results of a biopsy revealing the presence of melanocytic nevus. Wide excision of the nevus at the right auricular with cartilage exposure was performed and a split-thickness skin graft was used for the reconstruction of the auricle. Postoperative follow-up showed a good outcome.

INTRODUCTION

Congenital melanocytic nevus (CMN) is a benign proliferation of nevus cells (melanocytes) located in the epidermis, dermis, and other tissues. It may cause mutation of genes NRAS Q61 and BRAF V600E, and varies in severity from mild to life-threatening [1-3, 6]. According to Kopf, giant CMN (GCMN) is defined as nevi that will reach a diameter >20 cm in adult life. In addition, the presence and number of accompanying smaller (satellite) nevi should be recorded and classified into: 1) no lesion; 2) 1–20 lesions; 3) > 20 – 50 lesions; and 4) > 50 lesions. GCMN occurs in 1 per 500,000 births, and is associated with a 2% – 42% and 6% – 14% risk of transforming into a malignancy or developing into multiple myeloma, respectively. The available therapeutic modalities for GCMN include surgery and non-surgical, psychological, and/or clinical intervention with particular attention to discoloration, texture, or the surface of lesions [1, 4, 7-10].

GCMN occurring in the auricular area is considered rare. Moreover, reconstruction following large auricular skin defects frequently poses a surgical challenge. Esthetic concerns include symmetrical projection and maintenance of the shell-like shape. Postoperative complications may include contracture interfering with function, seroma, hematoma, infection, dehiscence, and keloid. Full-thickness skin grafts (FTSGs) and split-thickness skin grafts (STSGs) are alternative options for the coverage of large wounds, offering good functional and cosmetic results. Overall patient satisfaction with regards to the esthetic outcome is high (mean, 9.8). In addition, the rating provided by the surgeons is consistent with patient satisfaction [1, 4, 13].

CASE REPORT

A 6-year-old female was admitted to the CiptoMangunkusumo General Hospital following the appearance of black moles throughout the body especially in the ear, behind the ears, neck and right side of the face from birth. The mole grew larger with the advancing age, and the surface of the mole became thicker, hairy, and blackish in the areas of the face, ears and neck. A biopsy conducted by a dermatologist revealed the presence of melanocyticnevus. Hyperpigmentation appeared in the right auricle, preauricular and post auricula, mastoid area and neck with size > 40 cm, rough surface, and hypertrichosis without tenderness (Figure 1). There were >50 satellite lesions throughout the body. The ear canal, tympanic membrane, and audiometric examinations were normal.

Figure 1. The patient with GCMN. Appearance of satellite nevi on patient's face and neck (left picture) and appearance of GCMN on right auricle, right side of the face and behind the right ear (right picture).

The patient was diagnosed with GCMN. We performed wide excision of the nevus at the right auricular area until the mastoid area, followed by reconstruction using STSGs from the thigh area placed in the preauricular, auricular, post auricular, and mastoid areas to the right area of the coli (Figure 2). Postoperatively, the patient was hospitalized for 5 days with daily skincare and administration of antibiotics, and educated regarding wound care.

Figure 2. Wide excision and reconstruction with STSGs. Wide excision procedure of right GCMN (right auricular until mastoid area) with preservation of auricle cartilage (Picture A, B and C). Reconstruction of defect with suturing of STSG (Picture D and E).

Figure 3. The patient after surgery.

Follow-up was performed in out patient clinic 10 days postoperatively. The tie-over of the graft was removed, the condition of the graft appeared good, and there was no seepage of blood or active bleeding. The stitches were partially removed on day 14. A wet area was observed at the preauricular and neck areas, and treated with amnion.

Follow-up performed 45 days after surgery showed that the wound was dry and the appearance of the epithelium was good (Figure 3). The stitches in the auricular area were the parts removed last to maintain the shape of the cartilage. The patient was subsequently referred to the Dermatology Department for potential laser treatment.

DISCUSSION

GCMN of the ear is a very rare condition. Surgery is currently the treatment of choice for large-sized lesions. It is paramount to note the following in procedures for children: 1) donor skin, 2) grafting technique, 3) early postoperative care. The nevus must be cautiously excised to fully preserve the underlying perichondrium and avoid the presence of residual nevus. For larger nevi, the treatment plan divides the ear into esthetic units as follows: 1) concha, external auditory meatus, and ear canal; 2) antihelix, crura, and scapha; 3) helical rim; 4) lobule; 5) posterior auricular surface; 6) the region of non-hair-bearing skin above and posterior to the ear adjacent to the scalp; and 7) preauricular area (Figure 4) [1, 2, 12].

The reconstruction of large auricular skin defects frequently poses a surgical challenge. Esthetic concerns include symmetrical projection, maintenance of the shell-like shape of the helix, matching the skin color and textures, size discrepancies, presence and symmetry of the tragus as well as the contour of the antihelix, and the concha bowl. In the auricular region, options for the closure of defects typically include second intention healing, posing a risk of cartilage desiccation and webbing of the contoured surface of the ear [13].

Figure 4. The esthetic units of the ear.

Tailor suturing in the area of auricular is challenging; therefore, it is recommended that the procedure is performed at a sufficiently advanced age (at least at 6 or 7 years of age), for the cartilage to be strong and capable of supporting the graft. The graft can also assist in the evaluation of the risk of recurrence and malignant alterations. FTSGs are an alternative to skin flaps for the auricular region; however, the thickness of FTSGs may be inappropriate for the thin skin of the ear. Failure of FTSGs has been reported in 14% – 30% of reconstruction cases. It has been suggested that STSGs allow rapid coverage of large wounds and offer excellent graft survival. The semitransparent characteristics of STSGs are ideal for covering the wound bed following the excision of an aggressive tumor, as they facilitate the detection of potential recurrence. Notably, thin STSGs match the thin skin of the cartilaginous ear better versus FTSGs, thus offering a distinct advantage [2, 13].

In this case, GCMN of right auricular was treated with wide excision exposing the cartilage, followed by reconstruction of the auricular area using STSGs. Evaluation performed 45 days after surgery showed good outcome.

CONCLUSION

GCMN is a very rare case and require surgical management. Reconstruction of auricle afterwide excision of GCMN is a challenging procedure regarding esthetic, anatomical structure with preservation of auricle cartilage. STSG is the main choice for auricle reconstruction in this case since it allows rapid and match coverage and facilitate detection of potential recurrence [1, 13].

ABSTRACT

Parry–Romberg syndrome (PRS) is a rare degenerative disease characterized by unilateral, slow, and progressive atrophy of the facial tissue (including muscle, bones, and skin). Patients with this syndrome often develop a deviated nose. Such condition may lead to various aesthetic and functional issues. Septorhinoplasty plays a central role in the successful management of deviated nose. Here, we discuss the management of deviated nose in a patient with PRS along with evaluation of its characteristics, etiology, and pathophysiology. An 18-year-old female with deviated nose and the angle of her mouth toward the right side of the face underwent septorhinoplasty and labioplasty. Post surgery, functional and aesthetic improvements were observed in the deviated nose and facial asymmetry.

INTRODUCTION

Hemifacial atrophy or Parry–Romberg Syndrome (PRS) is a rare degenerative disease. It is characterized by slow and progressive unilateral atrophy of the facial tissues, including the skin, subcutaneous fat, muscle, cartilage, and bone. This condition was described for the first time by Parry and Romberg in 1846. The onset of disease occurs during the first decade of life. It slowly progresses for 2–10 years, reaching a stable phase between 18 and 21 years of age [1]. The extension of the atrophy is frequently limited to one side of the face. However, it may occasionally spread to the neck and one side of the body. Occasionally, ocular involvement, deviation of mouth and nose to the affected side as well as unilateral exposure of teeth is also noted. Moreover, patients may present with some neurological complications (e.g., trigeminal neuralgia, facial paresthesia, severe headache, and contralateral epilepsy). Identification of antinuclear antibodies in the serum suggests that the PRS is a kind of localized scleroderma.

CASE REPORT

An 18-year-old girl presented to our hospital with complaints of facial asymmetry and deviation of the nose and angle of mouth to the right side of face. After the age of 7 years old, slow shrinking of the right side of the face was noted by her mother. No symptoms of neurological disturbances or systemic problems were identified. Family history was negative for similar complaints. Additionally, no incidences of trauma or infection were observed to coincide with or precede the onset of the deformity. Clinical examination revealed narrowed right nasal cavity, deviated septum, and eutrophy of the inferior concha. Nasal analysis showed deviation of the nasal axis to the right side ($< 150^\circ$), deviated tip from the basal view, saddle nose below the rhinion axis, and a nasofacial angle of 30° (Figure 1). Rhinomanometry demonstrated higher resistance than normal during inspiration. Additionally, lower air flow in both the right and left nostril at 75 Pa (0.57 Pa/cm³/s and 90.42 Pa/cm³/s, respectively) was noted. The scores of nasal obstruction symptom evaluation and peak nasal inspiratory flowmetry (PNIF) were 35 and 90, respectively. The patient was evaluated by an ophthalmologist and a rheumatologist, and no abnormality was identified. Laboratory examination such as anti-nuclear antibody (ANA) titer in September 2015 was positive, whereas in February 2016, it was negative. Additionally, CRP and ESR were within normal limits. The patient did not receive any medical treatment for immunity disturbance.

In July 2016, the patient underwent septorhinoplasty and labioplasty (Figure 3). Three months after surgery, no nasal congestion was observed, and clinical examination showed a wide right nasal cavity, undeviated septum, and inferior concha eutrophy (Figure 4). An improvement in nasal analysis was observed, with increased angle of nasal axis (174°), no deviated nasal tip, and nasofacial angle post surgery of 40° . Rhinomanometry showed significant changes, with an increased nasal air flow and a lower resistance during inspiration in both the right and left nostrils at 75 Pa (0.41 Pa/cm³/s and 0.37 Pa/cm³/s, respectively) was noted. The scores of nasal obstruction symptom evaluation and PNIF were 10 and 120, respectively.

Figure 1. Pre-operative assessment. Nasal analysis showed a nasal axis deviated to the right from the frontal, lateral, and basal view.

Figure 2. Three-dimensional CT Scan. CT Scan showed no abnormality in the hard tissue, and slight thinning of the soft tissue on the right side of the face, starting from the forehead and buccal cavity.

Figure 3. Intraoperative procedure.

Figure 4. Assessment after three months of surgery.

Nasal analysis showed an improvement in the deviation of the nasal axis from the frontal, lateral, and basal view.

DISCUSSION

In a previous study by Deshingkar et al., it was described that the onset of PRS is insidious. The disease generally manifests itself as an atrophy, with onset during the first decade of life. Prior to becoming quiescent and stabilizing, the syndrome slowly progresses [1]. In this case report, the patient complained of facial asymmetry and deviation of nose and angle of mouth to the right side of face since she was 7 years old. Additionally, 3 years ago, the patient developed nasal congestion. Such findings prove that symptoms slowly develop over the years. In a previous study by Aydin et al., it described that patients with PRS may manifest ophthalmic, and neurological complications. However, the study patient had no symptoms of neurological disturbance and had normal vision [2].

A report by Patel et al. stated that the treatment of PRS should be initiated only after the disease stabilizes [3]. Surgical treatment options depend on the side of atrophy and deformity [3]. The study patient had the deviation of the nose and upper labia to the right side. Consequently, for aesthetic and nasal congestion reasons, the patient underwent plastic reconstruction. Septorhinoplasty and labioplasty were performed after the age of 18 years to ensure that the disease has stabilized and facial growth has slowed down. Of note, performing surgery during facial growth would affect the shape of the nose [2]. Although a deviated nose is one of the greatest challenges in septorhinoplasty, it can be treated with appropriate surgical procedures. Using a precise nasal analysis pre-surgery, the patient was found to have

a C-shape deviation. The anterior rhinoscopy showed a deviated right nasal septum and the rhinomanometry showed resistance during nasal inspiration.

To reduce the congestion caused by deviated nose, the septum had to be reinforced and supported in a midline position. The spreader graft was placed following osteotomies, to secure the cartilage in a midline position. The spreader graft was important to smooth the brow-tip aesthetic line and prevent or correct midvault collapse by stenting open the internal nasal valve. As a consequence, medial displacement of the upper lateral cartilages was prevented. The caudal extension graft was used to enhance nasal tip dynamics by controlling the projection, rotation, and strength of the tip. The alar batten graft was used to reinforce the weakness of the lower lateral cartilage, thereby improving nasal patency in correlation with the nasal valve area. Treatment for the atrophy of the cheeks and forehead will be performed by a dermatologist using hyaluronic filling. Four months after surgery, the patient was in good clinical and aesthetic condition.

CONCLUSION

In conclusion, PRS manifests as an atrophy leading to a variety of either or both aesthetic and functional problems. In the study patient, septorhinoplasty was used to successfully manage the deviated nose caused by PRS. The functional septorhinoplasty provided structural support by means of autologous grafts to preserve and augment the nose without compromising aesthetic and functional results.

Chapter 325

USE OF NASOLABIAL AND NASAL SEPTAL FLAPS FOR UNILATERAL LOWER-THIRD NASAL DEFECTS

***Mirta H. Reksodiputro, Satria Dipo Putra Asmoro,
Dini W. Widodo and Trimartani Koento****

ORL- HNS Department, University of Indonesia, Jakarta, Indonesia

ABSTRACT

The nose is the most prominent structure in the center of the face and plays an important role in the aesthetics of the face. Nasal defects in the dorsum, ala nasi, nostrils, columella, or septum due to trauma, animal bites, and tumor can lead to loss of function and decrease in aesthetic value. Nasolabial and nasal septal flaps are used for the reconstruction of nasal defects after mass extirpation in the lower third of the nose, particularly in cases of ala nasi defects. Here, we report the case of a patient who underwent reconstruction with a combination of nasolabial and nasal septal flaps for an ala nasi defect due to mass extirpation for basal cell carcinoma. We also conducted an evidence-based literature search tailored to the case.

Keywords: Nasal defect, nasal reconstruction, nasolabial flap, nasal septal flap

INTRODUCTION

Nasal soft tissue can be deformed by accidents, surgical trauma, human or animal bites, tumors, and leishmaniasis. Basal cell carcinoma is rather common, with ~80% of the cases occurring in the head area, of which 40% occur in the skin of the cheeks and nose. Treatment with surgery in these cases often produces nasal defects [1]. External nose surgery is performed to correct the nasal defects, improve the aesthetic appearance of the nose and breathing, and restore the patient's mental health and self-confidence. However, ala nasi reconstruction for deep or broad defects is rather challenging from an aesthetic as well as a

* Corresponding Author's Email: trimartani@yahoo.com.au.

functional perspective. Nasal defects can be reconstructed using many techniques, the best being the use of nasolabial flap, which has a rich blood supply and a suitable texture and color, although it is associated with high donor area morbidity [2]. Nasolabial flap is very useful in ala nasi defect reconstruction [3]. This flap is very well done in elderly patients because it has more flexible skin, and more suitable color evenly. It's difficult to do for patients with hairy skin [4]. In case with large alae nasi defect, it can be combined with nasal septal flap because it has good blood supply. The septal mucoperichondrium can be used for one side in reconstruction [5].

CASE REPORT

A 56-year-old woman underwent wide excision for basal cell carcinoma removal in October 2015 at the Oncology Surgery Division of Dr. Cipto Mangunkusumo Hospital, Jakarta, Indonesia. Reopening of the surgical wound caused a defect on the right side of the lower third of her nose (Figure 1). She did not complain of nasal congestion, recurrent nosebleeds, or pain in the wound. Local examination revealed a $3 \times 1 \text{ cm}^2$ defect in the lateral nasal dorsum toward the right nasal ala nasi, involving the visualized base of the inferior turbinate mucosa, the right nasal septum, and some of the medial turbinate. The defect edge was hyperemic and dry, with a network of clefts on the edge of the defect, nasal dorsum, and right nasal collumela. An asymmetrical deflection nasal tip appeared to the right. The trichion, glabella, nasion, rhinion, tip, and subnasal region were not in a straight line. There was no hematoma, edema, laceration, excoriation, or active bleeding.

Reconstruction surgery was performed on November 1, 2016, in the plastic reconstruction division of the otorhinolaryngology outpatient clinic. The island flap surgical technique used a combination of nasolabial and nasal septal flaps. An ear cartilage graft was used as a base support, and the nasal septal mucosa was used to line the nasolabial flap (Figure 2). During follow-up on day 7 postsurgery, the defect was found to be closed, and the nasal septal flap showed growth with no obstruction in the nasal cavity (Figures 3 and 4). During follow-up at 2 months postsurgery, the patient made no complaints of pain, nasal congestion, or runny nose mixed with blood. There was no edema, hematoma, hyperemia, or pus. In addition, there was minimal scar tissue in the surgical wound. Nasoendoscopic examination showed that the surgical wound appeared well; the nasal septal mucosa had formed with good vascularization; the nasal septal flap appeared well; and there was no hematoma, hyperemia, pus, edema, or perforation (Figure 5).

DISCUSSION

The nasolabial flap is very useful in ala nasi defect reconstruction, particularly in the elderly, because of its proximity, suitable color, and ease of use in the nasal recipient area [6]. In addition, the nasolabial flap is rich in blood vessels, including angular arteries (facial artery branches), infraorbital arteries, facial arteries, and infratrochlear arteries, and it is easy to anastomose between the main branches of the blood vessels [9]. Nasolabial flap can be combined with nasal septal flaps. Brian, Drisco. defek yang cukup besar pada hidung, dapat

digunakan jahir mukoperikondrium septum pada kaudal septum [7]. Jabir ini di suplai darah dari percabangan arteri labialis superior [8].

Figure 3. Day 7 postsurgery follow-up.

Figure 4. Nasoendoscopic examination on day 7 postdurgery follow-up. Nasal septal flap growth looks good.

Figure 5. Two-month postsurgery follow-up. The nasal septal flap growth looks good, with no hematoma, hyperemia, pus, edema, or perforation.

In the island flap technique, the nasolabial flap is derived from the cheek area for the reconstruction of nasal defects that are not too large [6]. The nasal septal mucosa is taken as a lining, and an ear cartilage graft is placed above it as support on the contralateral side, making a sandwich [7]. Septal and ear cartilages are used to replace missing parts of the nose and provide good support because of their thin and flexible contours [10].

For a large nasal defect, the mucopericondrium from the nasal septal flap at the caudal septum can be used, which gets blood supply from superior labial artery branches. If needed, most of the one-sided mucopericondrium can be used for reconstruction [2]. The ipsilateral nasal septal flap can be used as a close pedicle, containing superior labial artery branches. This flap is thin and physiological and can be used for defects of the caudal third of the nose [11].

CONCLUSION

This paper had a case female, 56 years old with right alae nasi defect after tumour extirpation. Reconstruction is performed using nasolabial flap combined with nasal septal flap and ear concha cartilage for base. There was good result for aesthetic and function after two month evaluation. Nasolabial and Nasal Septal Flaps are good option for reconstruction of nasal defect with good and favourable results especially in elderly case.

SUPERNUMERARY NOSTRIL: A RARE CONGENITAL ANOMALY

Dini Widiarni Widodo* and Rindy Yunita Pratamisiwi

Department of Otorhinolaryngology – Head and Neck Surgery,
Faculty of Medicine Universitas Indonesia/Cipto Mangunkusumo General Hospital,
Jakarta, Indonesia

ABSTRACT

Supernumerary nostrils are an extremely rare congenital. The purpose of this study is to prepare a standardized procedure for repairing supernumerary nostrils, and to discuss the probable psychological effect on the patient. Fistulectomy and cartilage graft from the ear were performed to reconstruct the accessory nostril. Surgery was performed at a young age to prevent further disfiguration and to optimize psychological well-being. The result of this study is the wound showed good healing progress over the lateral side of the nose. Although the symmetry between the two nostrils was not ideal, it was acceptable. The repair aims to create a functioning and normal-appearing nose with minimal deformity. The extra nostril can be excised during fistulectomy. The patient can also be offered social skill training to improve their self-esteem and family acceptance and support are important in the rehabilitation of children with facial disfigurations.

Keywords: supernumerary nostril, accessory nostril, psychological effect

INTRODUCTION

A supernumerary nostril is an extremely rare congenital deformity. Also known as triple nostrils or accessory nostril, supernumerary nostril is defined as an abnormal nostril located above the normal nostril. The specific cause and development of supernumerary nostril are not known. The anomaly seems to develop from a localized abnormality of the lateral nasal

* Corresponding Author's Email: dini_pancho@yahoo.com.

process at an early embryonic stage. Various types of the anomaly exist, and different surgery techniques to each are required, but there is still no generally accepted method of repair. The goal of repair is to create a functioning and normal-appearing nose with minimal deformity.

CASE PRESENTATION

A 10-year-old male child, who had a supernumerary nostril located beside his left nostril since birth, was referred to our department. He had no history of nasal obstruction. According to his mother, her pregnancy, the child's birth, and his development were uneventful. The patient had no other congenital abnormalities, and there were no reports of this type of deformity in either parent's family history.

On physical examination, the patient had two nostrils on the left side and the normal ipsilateral nostril was a little smaller than that on the other side. The diameter of the accessory nostril was 2 mm, and there was no discharge from any of the nostrils. We found no inferior and middle turbinate in the accessory nostril and no connective structures to the normal nostril. There was also no upper lateral cartilage in the accessory nostril; thus, the nostril felt soft on palpation. There was fibrous tissue without any columellar structure between the left and accessory nostrils. The nasal mucous lining appeared normal, and the patient was classified with type 3-a supernumerary nostril.

The surgery was performed under general anesthesia. The inner nostril was incised following the accessory nasolabial fold, and a left rim incision was then performed. The tissue between the vestibulum and the accessory nostril was widely undermined. No nasal alar and columellar structures were found during the surgery; therefore, alar reconstruction using ear cartilage was planned.

Figure 1. Patient with supernumerary nostril.

The left ear concha was marked and dissected. The cartilage was cut into a $0.5\text{ mm} \times 0.5\text{ mm}$ piece and then inserted in the undermined vestibulum area to form a normal ala. The remaining subcutaneous and skin tissues were then sutured tightly to prevent hematomas.

The nostril size was adjusted with reference to the size of the normal nostril. The incision was sutured using 5-0 Prolene. The new ala was fixated using aluminum foil paper, and a small piece of nasogastric tube was inserted in the nostril as an internal stent, which was then removed after 3 days.

The wound showed good healing progress over the lateral side of the nose. The symmetry between the two nostrils, although not ideal, was acceptable. No hematoma was observed on the left ear, and the incised area showed no sign of infection. The patient and his parents were satisfied with the result, which boosted his confidence.

Figure 2. Intraoperative procedure.

Figure 3. Postoperative result.

DISCUSSION

Supernumerary nostril is an extremely rare type of congenital nasal anomaly with unclear etiology [1]. The first reported case was published in 1906 by Lindsay, who described a patient with bilateral supernumerary nostrils. Most reported cases of supernumerary nostrils have been unilateral, and were associated with other craniofacial malformations, such as a facial cleft [1-3]. A supernumerary nostril may or may not communicate with the ipsilateral normal nasal cavity, depending on the extent of the anomaly's progression. This condition should not be confused with the double nose deformity, which has two septa, four nostrils, four alae, and four nasal cavities [1-3].

Over the past 5 years, four cases of supernumerary nostril have been documented in English. In 2014, Sah et al. [4] reported a case with an accessory nostril located above the left nostril, which was repaired with an elliptical incision and fistulectomy technique. Trimartani and Widayanti in 2015 [5] and Choi et al. [3] in 2016 reported cases with a left accessory nostril treated by fistulectomy. Further, Asadi et al. [6] reported a case with a supernumerary nostril that was treated using an external rhinoplasty approach.

The preoperative workup for supernumerary nostril cases includes a detailed history with special attention to the prenatal course. A comprehensive physical examination is performed to rule out other craniofacial anomalies [7], and the diagnosis is made based on the clinical appearance, physical examination, and histological features of the accessory nostril [2]. Consideration of imaging results such as those of computed tomography scans or magnetic resonance imaging to rule out any intracranial communication or skull base defect is balanced with the risk of anesthesia, which is required for imaging [7].

The scarcity and variation of supernumerary nostrils call for innovation during surgical repair. The goal of repair is to create a functioning and normal-appearing nose with minimal deformity. It is vital to resect the entire fistula tract and to preserve the perviousness of the normal nostril. Additionally, the redundant nasal tract should be eliminated, the nasal width reduced, and the alar base repositioned, all the while maintaining the natural alar skin [7].

Most of the above studies advocated that corrective surgery be performed at a young age to prevent any possible alar deformity or deformation of adjacent structures, thereby minimizing related psychological effects [8].

An imperfect appearance may result in overt teasing, bullying, and unwanted questioning. Social responses may also take the form of more subtle modifications in normal patterns of verbal and non-verbal interactions, such as facial expressions. These unfavorable social responses are the result of stigma, where outsiders subconsciously judge an individual negatively because of their imperfect appearance. Individuals affected by supernumerary nostril who are dissatisfied with or who are unrealistic about their appearance need to be identified. These individuals are "at risk" for developing low self-esteem and could be offered some social skills training to improve their self-confidence and increase their self-esteem [8].

The family environment is an important aspect in the rehabilitation of children with facial deformities. The attitudes, expectations, and degree of support shown by parents are likely to have an enormous influence on a child's perception of their impairment. Surgery for disfigurement usually results in increased self-esteem, self-confidence, and satisfaction with appearance, irrespective of whether an objective improvement is detected by independent observers. Unrealistically high expectations for surgical improvement can result in

dissatisfaction with post-surgical results; therefore, families should be counseled extensively pre-operatively to identify cases where this may be a problem [8].

CONCLUSION

The documented cases of supernumerary nostril until now are still inadequate. To determinate the embryological implications, anatomic presentations and possible additional anomalies with accessory nose, cases need to be further investigated. We aimed to share this rare congenital anomaly within medical field. In this rare deformity, surgery should be performed at an early age to avoid severe impact on the nasal cartilages because of the fistula, deformation of adjacent structures, and the psychologic effects.

OBJECTIVE MEASURES IN FUNCTIONAL SEPTORHINOPLASTY: TWO CASE REPORTS OF NASAL FORM AND NASAL VALVE RECONSTRUCTION

Trimartani Koento¹, Tiara Melati² and Mirta H. Reksodiputro^{1,*}

¹Department of Otorhinolaryngology Head and Neck Surgery,
Plastic Reconstructive Sub Division, Faculty of Medicine, University Indonesia,
Dr. Cipto Mangunkusumo Hospital, Jakarta, Indonesia

²Department of Otorhinolaryngology Head and Neck Surgery, Faculty of Medicine,
University Indonesia, Dr. Cipto Mangunkusumo Hospital, Jakarta, Indonesia

ABSTRACT

Nasal valve, which is the narrowest area in the nasal airway passage, is responsible for about half of the total nasal airway resistance. Functional septorhinoplasty is used to achieve an esthetic shape of the nose while preserving adequate nasal and breathing function. Nasal complaints are subjective; thus, objective measurements obtained through active anterior rhinomanometry are needed to correctly identify nasal valve incompetence. We present reports of two cases where changes in nasal airflow and resistance were objectively assessed before and after functional septorhinoplasty using an alar batten graft. Significant changes were observed postoperatively. Improvement was confirmed by assessment of subjective symptoms of nasal obstruction and rhinomanometry data.

Keywords: rhinomanometry, septorhinoplasty, alar batten graft, nasal valve

INTRODUCTION

It is often difficult to objectively quantify the outcomes of functional and esthetic nasal surgery (septoplasty, rhinoplasty, nasal valve surgery, turbinateplasty, and septorhinoplasty)

* Corresponding Author's Email: citamirta@yahoo.com.

[1], as traditional outcome measures rely on quality-of-life and patient satisfaction. The development and validation of objective measures may allow quantification of surgical outcomes. As nasal form and function are closely intertwined, quantitative assessment can better define this relationship and the effects on these parameters following nasal surgery. Rhinomanometry is an objective measure of nasal airflow and resistance that can be applied to outcome-based research to allow improved comparisons of results across studies. Further development of these objective measures can potentially lead to the identification of clinical predictors for surgical success or the development of standard criteria for surgical decision support. This information is useful not only within academia but also within commercial healthcare, given the mounting external pressure for quantifiable outcomes, particularly in the field of facial plastic surgery, which is increasingly being faced with challenges for insurance approvals and justification of procedures. Thus, the need for objective data will only continue to grow.

Several characteristics of objective assessment techniques, such as nasoendoscopic evaluation and rhinomanometry, are important to achieve accurate reproducible results and to ensure cost-effectiveness. Many available objective measures for functional nasal surgery are lacking in one or more of these characteristics, thereby limiting their routine clinical use. However, advances in computed imaging technologies, such as computed tomography scan (CT scan), have facilitated the development of innovative objective assessment tools for nasal surgery. In this article, we have presented an overview of objective measures in both esthetic and functional nasal surgeries and discussed the assessment of objective outcomes of nasal form and function is discussed.

CASE 1

A 24-year-old woman presented with a 5-year history of debilitating nasal obstruction. No other nasal or throat symptoms were noted. On physical examination, there was no nasal deformity or positive sign of Cottle's maneuver (Figure 1). A rigid nasal endoscopic examination showed narrowing of the nasal passages; the internal nasal valves were narrowed, and the inferior turbinates were edematous without septal deviation. The results of anterior active rhinomanometry showed moderate obstruction of right nasal airflow (Figure 2) with a significant reduction in the flow at rest and maximum respiration (Table 1).

Nasal valve incompetence was addressed through septorhinoplasty, multiple outfracturing of the inferior turbinates, and an alar batten graft. The graft donor site was the cartilage from the left auricular conchal cavity; the site was closed and secured with through-and-through sutures. The patient was discharged the following day. One week postoperatively, the patient had no nasal obstruction. A nasal endoscopic examination revealed a broad nasal passage and widened internal nasal valve areas (Figure 3). A second rhinomanometry examination performed at 2 weeks postoperatively revealed a significant improvement in the right nasal airflow at rest and maximum respiration with enhanced nasal resistance (Figure 4, Table 2).

CASE 2

A 45-year-old male presented with a chief complaint of nasal obstruction with a history of nasal closed reduction 6 months ago due to an accident (Figure 5). On physical examination, there was no deformity of the nose, with only a scar observed in the right medial canthus. Cottle’s maneuver was positive. Nasal endoscopic examination revealed a deviated septum superiorly and collapsed ala nasi during respiration, which reduced the internal nasal valve area. Nasal incompetence in this patient was addressed by septoplasty, and an alar batten graft was placed via the endonasal approach. The patient was discharged the next day, and follow-up examination at 1 week postoperatively was improved, as seen from the nasal endoscopic comparison before and after surgery (Figure 6).

Figure 5. Frontal preoperative view.

Figure 6. Nasal endoscopic findings: (A) pre- and (B) postoperatively.

DISCUSSION

Objective measurement of nasal obstruction is important to determine a successful surgical outcome. There are many studies that show discrepancy between subjective and objective findings of nasal patency [1]. Therefore objective tools must be reproducible, be able to exclude a mucosal diagnosis, and correctly identify relevant constraints. In the United States, the annual cost of treatment of nasal obstruction exceeds 5 billion USD, with nasal surgery accounting for more than 60 million USD [2]. Rhinomanometry and acoustic rhinometry are expensive, time-consuming, and uncomfortable to the patient [3, 4].

According to Hsu et al. [5], the visual analog scale, the nasal obstruction symptom evaluation questionnaire, and anterior active rhinomanometry are useful tools to assess subjective complaints regarding nasal patency following septoplasty. Rhinomanometry is used to obtain information regarding nasal airflow and resistance. All three of these modalities are helpful in determining the candidacy and success of septoplasty. Bohluli et al. [6] have described the specific equipment and skills required for rhinomanometry, acoustic rhinometry, and computed tomography. The external nasal valve efficacy index by simple photography, which utilizes software to calculate the cross-sectional nostril at rest and respiration, is a relatively simple method that can be routinely performed preoperatively and can be used to document every stage of therapy [6].

Miman et al. [7] identify and classify the shape of the internal nasal valve using nasal endoscopy. In light of the advances in smartphones, Surda et al [8] perform image analysis to measure the angle and cross-section area of the internal nasal valve. Lee et al. [9] and Moche et al. [10] both studies uses standard CT scan to identify and measure the internal nasal valve.

According to Spielmann et al. [11], identification of the specific underlying cause of nasal valve incompetence is necessary to achieve successful reconstruction. Thus, the most appropriate technique may be to strategically address each cause, and the causes vary across cases. While selecting the technique, long-term advantage to the patient must be considered. Furthermore, Spielmann et al. [11] have recommend routine nasal airflow examination both pre- and postoperatively.

A combination of objective tools such as facial photos, Cottle's maneuver, nasoendoscopic findings, and anterior active rhinomanometry is essential for the diagnosis of nasal obstruction due to incompetence of the nasal valve. Such tools allow specific identification of the area of the lesion and are relatively reproducible. Although rhinomanometry may not be available everywhere and access is limited in many facilities,

facial photos, Cottle's maneuver, and nasoendoscopic findings provide integral information, which greatly impacts the selection of the reconstruction technique.

ABSTRACT

Patients with laryngopharyngeal reflux frequently experience refractory voice-related symptoms that are nonresponsive to antireflux therapy. New options, such as voice therapy, are alternative treatments for laryngopharyngeal reflux. To evaluate the effect of voice therapy in addition to medical antireflux treatment in a patient with laryngopharyngeal reflux with persistent voice-related symptoms with the use of subjective assessment by the Reflux Symptom Index and the Voice Handicap Index and objective evaluation of the vocal cords by laryngovideostroboscopy. A 48-year-old woman with laryngopharyngeal reflux presented with hoarseness and a sensation of lump in her throat for the previous 6 months. The patient had taken a proton-pump inhibitor twice a day and undergone lifestyle modification for 6 months, but there was no significant improvement. Voice therapy along with antireflux therapy and lifestyle

* Corresponding Author's Email: zulka.elvie@gmail.com.

modification was then conducted. Evaluation by subjective and objective assessments showed a significant improvement after the comprehensive treatment strategy. After voice therapy and the use of a proton-pump inhibitor, the Reflux Symptom Index decreased from 19 to 10, and the Voice Handicap Index lowered in functional (from 3 to 0) and physical (from 8 to 6) subscales. The stroboscopic findings showed significant improvement in mucosal wave (from 10% to 60%), amplitude (from 20% to 40%), open-closed phase, phase symmetry, and periodicity. Voice therapy should be considered as an adjuvant treatment to antireflux therapy and lifestyle modification in patients with laryngopharyngeal reflux presenting with refractory voice-related symptoms.

Keywords: Antireflux therapy, laryngopharyngeal reflux, laryngovideostroboscopy, RSI, VHI-10, voice therapy

INTRODUCTION

Laryngopharyngeal reflux (LPR) is defined as the backflow of gastric contents into the larynx and pharynx [1]. LPR may be manifested as laryngeal symptoms such as cough, throat clearing, hoarseness, and globus, as well as signs of laryngeal irritation on laryngoscopy [2]. LPR occurs in 4% to 30% of patients who visit otolaryngology departments [3–5]. Up to 71%–79% of the patients with LPR complain of nonspecific symptoms, including hoarseness [6, 7].

Voice problems in LPR patients are best evaluated by subjective and objective approaches. By assessing the patient early both subjectively, using the Reflux Symptoms Index (RSI) and a 10-item Voice Handicap Index (VHI-10), and objectively, using laryngovideostroboscopy, a more efficient model for evaluation and treatment of the patient may be achieved. Vocal fold pathology in LPR is best diagnosed by laryngovideostroboscopy. Among the laryngostroboscopic findings, vocal fold edema has been suggested as the main factor affecting vibration of the vocal folds, leading to hoarseness. In addition, hyperadduction of the true vocal and vestibular folds, the presence of glottal chinks of different lengths, and reduced amplitude and mucosal wave are the main stroboscopic findings [8–11].

Treatment of LPR patients with refractory voice problems is very challenging. Proton-pump inhibitors (PPIs) are still the most effective agents for the treatment of LPR. Belafsky et al., [12] reported that symptom resolution in LPR occurred after 2 months of treatment with PPIs and that the physical findings improved more slowly after at least 6 months of treatment. Refractory voice-related symptoms of LPR that are treated by antireflux therapy have multifactorial causes. The negative loop highlighting the cough and throat clearing secondary to the subsequent accumulation of sticky mucus and globus sensations may be responsible for exacerbation of the tension applied to the mucosa and thus increase vocal microtraumas. Increasing force and subglottal pressure during phonation in the edematous vocal cords may lead to more damage of the mucosal structure. This improper technique of phonation is another factor that prolongs the healing process in injured vocal folds and may cause persistent voice-related symptoms in LPR patients [12–14].

Currently, voice therapy along with medical therapy is the mainstay of treatment for LPR patients with voice problems. The global objective of a program including direct and indirect therapy is the reduction or correction of improper use of the voice. The direct approach aims

to correct posture; reduce tension in the laryngeal and cervical muscles; promote respiratory control, efficient glottal closure, and resonant equilibrium; and improve articulation. The indirect methods include raising awareness of healthy vocal habits and their importance. Voice therapy may also help to reverse mucosal changes secondary to acid reflux, inducing rapid resolution of symptoms and shortening the treatment period. Several studies have shown that voice therapy may improve RSI scores in LPR patients when used either with or without a PPI. Furthermore, behavioral voice therapy may result in alleviation of symptoms and reduction in RSI scores that do not occur with antireflux management only [15, 16].

The current study reports a case of LPR with voice disorder that did not respond to antireflux therapy. Voice therapy was conducted in addition to PPI therapy and resulted in many improvements in subjective and objective laryngeal assessment by RSI, VHI-10, and videostroboscopy. The aim of this study is to describe the importance of comprehensive therapy of PPI together with voice therapy in diminishing refractory voice-related symptoms in LPR.

CASE REPORT

A 48-year-old woman with chief complaints of hoarseness and a sensation of lump in her throat for 6 months came to the otorhinolaryngology outpatient clinic of the Ciptomangunkusumo Hospital. The patient had been previously diagnosed with LPR at a private hospital. She had taken a PPI (lansoprazole, 30 mg twice a day) and undergone lifestyle modification for 6 months; however, the symptoms did not diminish. She was then diagnosed with intractable LPR. The VHI-10 questionnaire, which has been validated for the Indonesian language, was used to subjectively evaluate the severity of the patient's dysphonia. At baseline, her VHI-10 score was 13; her RSI score was 19, with the highest scores for voice problems and globus sensation; and her RFS was 10. Neck palpation revealed increased tension of the extrinsic muscles.

The laryngovideostroboscopic evaluation showed an obvious decrease in the mucosal wave of up to 10%/10% and a decreased vibratory amplitude of up to 20%/20%. Supraglottic activity was 20% in the anteroposterior configuration. The periodicity was irregular, with closed phase dominant. There was phase asymmetry with "snake dance" appearance with posterior chink during the closed phase.

Voice therapy along with LPR medication and lifestyle modification was then advised. Voice therapy was tailored to this patient and constituted a combination of indirect and direct approaches. The indirect approaches included patient education, such as discussion of the impact of muscle tension on function, vocal hygiene, and counseling. The direct approaches included physiologic and symptomatic techniques to manipulate subsystems of voicing (respiration, phonation, and resonance). The voice therapy sessions were approximately 50 to 60 minutes in duration and were conducted weekly. All six sessions were completed in one and a half months.

After this comprehensive treatment, the patient was reassessed by RSI, VHI-10, and laryngovideostroboscopy. The VHI-10 showed good results after treatment, especially in the functional and physical subscales (Table 1). The RSI was successfully decreased into 10 with diminishing of voice problems (from 4 to 2 points) (Table 2). In contrast, the globus sensation

showed only minimal improvement after treatment (from 4 to 3). Laryngovideostroboscopic examination revealed improvement in the edges of the vocal folds and mucosal wave that reached 60%/60% after therapy (Figure 1 and 2). Amplitude, vibratory portion, supraglottic activity, periodicity, lengthening of the closed phase, and phase symmetry also improved after voice therapy and PPI (Table 3). However, the posterior gap during closed phase was still visualized.

Table 1. Voice Handicap Index (VHI-10) scores in a patient with refractory dysphonia due to laryngopharyngeal reflux before and after voice therapy

VHI-10 (Indonesian version)	Baseline	Follow-up
Functional subscale	3	0
Physical subscale	8	6
Emotional subscale	2	2

Table 2. Reflux Symptoms Index (RSI) scores in a patient with refractory dysphonia due to laryngopharyngeal reflux before and after voice therapy

RSI	Baseline	Follow-up
Voice problem	4	2
Clearing throat	2	0
Postnasal drip	3	3
Difficulty swallowing	3	0
Coughing after eating or lying down	0	0
Breathing difficulty	1	0
Annoying cough	0	0
Sensation of lump in the throat	4	3
Heartburn, chest pain	2	2
Total	19	10

Table 3. Evaluation of the vibratory function of the vocal cords in a patient with refractory dysphonia due to laryngopharyngeal reflux by stroboscopy before and after voice therapy

Stroboscopy parameters	Baseline	Follow-up
Mucosal wave (%)	10/10	60/60
Amplitude (%)	20/20	40/40
Glottic closure	Posterior gap	Posterior gap
Vibratory portion (%)	20/20	60/60
Supraglottic activity (%)		
Lateromedial	0	0
Anteroposterior	20	0
Vocal folds edge	Smooth-convex	Normal
Vertical level	On plane	On plane
Periodicity	Irregular	Regular
Open–closed phase	Closed dominant	Normal
Symmetry	Asymmetry	Symmetry

Figure 1. Vocal folds edge improved after voice therapy and proton-pump inhibitor therapy; left, before and right, after therapy.

Figure 2. The mucosal wave improved after voice therapy and proton-pump inhibitor therapy; left, before and right, after therapy.

DISCUSSION

According to the Stanford Voice and Swallowing Center Guidelines for LPR Disease, PPIs are the most effective agents for the treatment of LPR [13]. Successful treatment requires high doses for a prolonged period. The PPI should be taken twice daily for at least 6 months, depending on the severity of the LPR changes seen on examination. Improvement of symptoms is expected within 4 to 6 weeks. Usually, the visual signs of improvement according to laryngoscopy lag behind symptomatic relief by several months. Campagnolo et al., [17] recommended that pharmacologic intervention should consist of a minimum of 3 months of treatment with PPIs. Shaw et al., [18] and Pribuisiene et al., [19] analyzed the efficacy of PPIs such as omeprazole and lansoprazole and found a significant response of the laryngeal and voice-related symptoms in 8 weeks. Belafsky et al., [12] reported that symptom resolution occurred after 2 months of therapy with PPIs; however, the physical findings improved more slowly after at least 6 months of treatment. Park et al., [15] reported that 70% of the patients had a good response after 4 months of twice-daily PPI therapy. Thus, twice-daily PPI therapy for at least 4 months is reasonable, and the symptoms should improve by 2

months. However, the patient in this case report was given a PPI for 6 months with no significant subjective improvement.

The persistent voice-related symptoms of LPR treated by antireflux therapy have multifactorial causes. The negative loop highlighting the cough and throat clearing secondary to the subsequent accumulation of sticky mucus and globus sensations may be responsible for exacerbation of the tension applied to the mucosa and thus increase vocal microtraumas [14]. Increasing force and subglottal pressure in edematous vocal cords with abnormalities of vibratory function in reflux laryngitis may lead to more damage to the mucosal structure of the vocal folds. Improper techniques of phonation by LPR patients are another factor that prolongs the healing process in injured vocal folds. The refluxate also causes microtrauma to the lymphoid tissue (lingual tonsils), which may lead to hypertrophy and result in a persistent sensation of lump in the throat. In this condition, the persistent dysphonia caused by ineffective phonation techniques during speaking may induce microtrauma of the vocal folds, which worsens the voice-related symptoms and prolongs the antireflux treatment [14, 20].

Treating persistent vocal problems due to LPR after long-term antireflux therapy is very challenging. Few studies have evaluated the effectiveness of combined medical and voice therapy for this condition. The global objective of voice therapy is the reduction or correction of the improper use of the voice by a program including direct and indirect therapy. The direct approach aims to correct posture; relax the laryngeal and cervical muscles; promote respiratory control, efficient glottal closure, and resonant equilibrium; reduce voice symptoms; improve articulation; and reduce tension in the laryngeal muscles. The indirect methods include raising awareness of healthy vocal habits and their importance. Reposturing of the laryngeal anatomy using laryngeal manipulation, improving the range of motion in the neck and shoulders using manual intervention therapy, and standard physical therapy techniques in conjunction with voice therapy intervention may result in positive changes in outcome measures related to the voice. Lip trills, tongue trills, bilabial fricatives, humming, and phonation into tubes or straws have been used in speech clinics for the treatment of dysphonia. Among these techniques, trill techniques, particularly lip trills, are most commonly used [16].

Voice assessment scales are used to detect the effect of voice therapy in LPR patients. The VHI-10 is a validated voice-related quality of life questionnaire that is used individually to evaluate treatment effectiveness in benign voice disorders. Studies by Rosen et al., [21] and Craig et al., [22] reported that the VHI-10 was applied for the evaluation of treatment efficacy in voice disorders. In this case report, we used the Indonesian version of the VHI-10 that was validated and adapted by Trifani et al., [23]. Voice therapy along with medication resulted in improvement in the functional and physical subscales, but not in the emotional subscale.

Vashani et al., [24] reported that the RSI scores improved in patients who underwent voice therapy. Schneider et al., [16] reported improvements in globus, throat clearing, hoarseness, and postnasal drip after voice therapy in LPR patients, whereas a minority of patients reported improvement in gastroesophageal reflux symptoms (e.g., heartburn). This finding suggests that voice therapy effectively targets voice and laryngeal symptoms in patients with elevated RSI and VHI-10. In this case report, there was improvement in hoarseness and throat clearing, but globus and postnasal drip remained the same. Park et al., [15] showed that the symptom-associated scores (RSI and VHI-10) improved in a clinically significant manner and the time to recovery was shortened by 2 months after voice therapy in LPR patients. The authors also demonstrated that the combination of voice and PPI therapy

provided a significantly greater improvement in the RSI and VHI-10 scores than PPI alone in patients diagnosed with dysphonia due to LPR.

In the stroboscopic findings, the vocal folds in patients with LPR often show mucous dehydration, unlike that in individuals with normal phonation. Woo [20] reported that a “salt and pepper” appearance was often found in the vocal folds of patients with LPR due to mucous dehydration. This was followed by reduction of the amplitude and mucosal wave and lengthening of the closed phase during sustained phonation. This finding suggests that a great driving pressure was necessary during the phonatory gesture. In some circumstances, higher driving pressure leads to increased isometric tension on the vocal folds and presses one or both vocal folds inward and reduces the amplitude of vocal fold vibrations. In this case report, the amplitude of the vocal folds was decreased to 20%/20%. Asymmetric inward compression of the vocal folds results in the abnormal vertical level of the midmembranous portion of the vocal cords. This implies that an increased shear force is being applied to the vocal fold margin. It is thought that this high-acceleration vibration is the primary mechanism of phonotrauma that is responsible for the development of benign mucosal lesions such as polyps and nodules in patients with LPR. The possible muscular hyperfunctional effect may also be secondary to a surface inflammatory reaction in LPR. Other minor pathophysiological mechanisms may be involved in voice changes, such as edema of the supraglottic structures. In this case report, the stroboscopic findings revealed that the mucosal wave was decreased to 10%/10%. Woo [20] reported that the normal mucosal wave was about one-half to two-thirds from the visible oscillating vocal folds. A decreasing mucosal wave is a sign of decreased pliability, elasticity, and viscosity in the cordal cover. Leichen et al., [25] reported that reduced hydration of the SLP in LPR may be associated with a reduction of the thickness of the cordal cover, potentiating the stability and the decrease in the mucosal wave, which is highlighted in some clinical studies. The inflammatory process in SLP modifies the biomolecular composition and biomechanical properties of this layer. Thus, the cordal cover could be less compliant, more viscous, and rigid, thus impacting the quality of the mucosal wave of the vocal folds in LPR patients [20, 25, 26].

The increased viscosity also makes it more difficult to start and maintain movement of the vocal folds, and the increased rigidity makes it more difficult to maintain the stability of the pitch; both of these events lead to irregularities in the vibratory process. In this case report, the periodicity of the vibration of the vocal folds was quite irregular [20, 25, 26].

The smooth-convex edges of the vocal folds in this patient show any fluid extravasation process in SLP and edema in the basal membrane that may lead to a “hot-dog” appearance [20]. There was also a posterior gap during the closed phase in this patient. Woo [20] reported that a posterior glottic chink or midfold contact pattern was often found in the vocal folds of LPR patients. These findings lead to an abnormal vibratory process and may lead to lengthening of the closed phase, phase asymmetry, and irregular periodicity that worsens the quality of a patient’s voice. “Snake dance appearance” was revealed in this case report as a sign of the asymmetry of the open and closed phases during vibration [20, 25, 26].

Dehqan et al., [27] showed that voice therapy can cause positive changes in the regularity of vibration and suggested that there can be a decrease in excessive action of the laryngeal muscles and hoarseness. Halawa et al., [28] reported that among patients with dysphonia who had alterations in stroboscopic parameters, improvement in glottal closure, mucosal wave, vocal vibration, and asymmetry was found in 33.9%, 50%, 52.27%, and 68.75% of the cases, respectively, after voice therapy. In this case report, there was improvement of approximately

20% in the mucosal wave, amplitude, and anteroposterior supraglottic activity. There was also significant visual improvement in the periodicity, open–closed phase, and phase asymmetry after voice therapy together with PPI. We believe that these changes in the mucosal structure and vibratory function of the vocal cords led to subjective improvement in the RSI and VHI-10 in this patient.

CONCLUSION

Voice therapy, along with reflux medical treatment and lifestyle changes, is effective in reducing the symptoms in patients with persistent dysphonia due to LPR and should be included in the treatment of patients with LPR that fail to respond to antireflux management. Further research on the effect of voice therapy in LPR patients with dysphonia that do not respond to medical treatment, using subjective assessment tools (VHI-10 and RSI) and objective tools such as stroboscopy and voice acoustic analysis, should be conducted in the future.

Chapter 329

MAXILLARY FIBROUS DYSPLASIA RECONSTRUCTION AFTER MAXILLECTOMY

Dini Widiarni Widodo*, PhD and Razki Yorivan, MD

Department of Otorhinolaryngology Head and Neck Surgery, Faculty of Medicine
Universitas Indonesia – Dr. Cipto Mangunkusumo General Hospital, Jakarta, Indonesia

ABSTRACT

Fibrous dysplasia is frequently managed with open maxillectomy, and the technique employed depends on the location of the lesion. Mid-facial reconstruction after maxillectomy is a complicated and difficult process. Clinicians require expertise and must exercise caution when closing the defect, taking into consideration both aesthetics and function. Post-maxillectomy reconstruction using titanium alloplastic material has various advantages. To present a case of maxillary fibrous dysplasia treated with suprastructure maxillectomy followed by reconstruction to close the defect. Reconstruction uses titanium mesh plates and muscle slings, with the facial contour and tissues lost during the suprastructure maxillectomy taken into consideration. Various types of maxillectomy and post-maxillectomy defects have been classified with the aim of facilitating reconstruction and guiding the clinician through the process. The reconstruction of suprastructure maxillectomy using a titanium mesh plate and muscle sling is effective and produces good results in function and aesthetics.

INTRODUCTION

Mid-facial defect reconstruction is an intricate and complicated process and represents a major challenge during head and neck tumor surgery. Available management options are pedicle flap, implant, and free flap, which are often combined with transplantation. The main

* Corresponding Author's Email: dini_pancho@yahoo.com.

problem with mid-facial reconstruction is the wide range of defects caused by tumor resection. Corresponding defects not only affect the maxillary bone but also affect the surrounding tissues, facial bone, cranial bone, soft tissue, and orbital bone. An important aspect of maxillary reconstruction is the repair of the maxillary walls. Successful mid-facial reconstruction requires expertise in reconstruction using both implants and a flap to ensure good rehabilitation [1, 2].

Fibrous dysplasia is a fibro-osseous benign lesion with an unknown cause. Fibrous dysplasia lesions in the maxillary area eventually extend to the maxillary sinus, zygomatic bone, sphenoid, and orbital floor. Management of fibrous dysplasia requires taking into consideration the size and location of the lesion. Large lesions require surgical intervention, which may result in significant functional and cosmetic damage to the face and will indirectly affect the quality of life of the patient [3, 4].

This report presents information on a maxillary fibrous dysplasia case treated with suprastructure maxillectomy and subsequently reconstructed with a mesh plate and muscle sling.

FREQUENCY

The frequency of fibrous dysplasia is 1:30,000 individuals, and the disease comprises 2.5% of all bone tumors and 7.5% of all benign bone tumors. The incidence of monostotic fibrous dysplasia is evenly distributed in men and women. This type occurs more often than the polystotic type. The incidence of the polystotic type in men is thrice than that in women. Both types of fibrous dysplasia commonly occur in children and adolescents [5, 6].

Fibrous dysplasia was managed using maxillectomy techniques in 15.2% of 66 cases reported in 2016 in Nigeria. Reports published in 2006 in Malaysia describe the use of maxillectomy for 24 benign maxillary tumor cases, comprising 41% of all cases in the country. The data collected from 2000 to 2009 showed that 26.4% of 65 benign tumor cases were treated with maxillectomy [7–9].

ANATOMY AND PHYSIOLOGY

The mid-facial area includes some of the most prominent structures of the face and separates the oral and orbital cavities. This structure is a polyhedron bounded by skeletal bones. In addition to its structural anatomy, the mid-facial area has functional properties related to breathing, phonation, chewing, swallowing, vision, and smelling. This area has two maxillary bones in the form of polyhedrons separated by the middle part of the face covering the nasal region. The center includes facial features such as the nose, cheeks, and upper lip, whereas the back extends to the anterior skull base. The superoinferior region includes soft tissue and bone from the orbital cavity to the oral cavity, and the middle surface extends towards the temporal bone. This structure includes various tissues surrounded by muscles, skin, and mucosa [10].

An important structure in the mid-facial area is a pair of maxillary bones that join the intermaxilla to form the maxilla. The maxilla contributes to the formation of three cavity

walls, namely, the roof of the mouth, the base and lateral wall of the nose, and the medial orbital wall and base. The maxilla attaches to the lateral side of the zygomatic bone. The attachment consists of the base and lateral wall of the orbit, giving the cheek its distinct shape. The maxillary bone is also associated with the frontal and ethmoid bones, nasal bone, lacrimal bone, inferior nasal turbinates, palate, and vomer [1]. The orbit is a structure bordering the mid-facial region. The frontal bone is the superior boundary of the orbit, whereas the inferior boundaries of the orbit are the maxilla, palate, and zygomatic bone. The medial boundaries of the orbit are the frontal, lacrimal, and ethmoid bone. The lateral border is the zygomatic bone. The orbit is located inferior to the anterior fossa of the cranial base and superior to the maxillary sinus and is lateral to the nasal cavity. The anterior border of the orbit is the medial fossa of the cranial base and the temporal fossa (Figure 1) [1].

The mid-facial area has a structure called the support wall. This wall functions to maintain the mid-facial area under normal conditions. This support wall is broadly divided into the vertical and horizontal support walls. The vertical support wall is composed of the nasofrontal, pterygomaxillary, and zygomaticomaxillary borders. The three borders serve as the foundation that maintains the mid-facial area in an upright position, forming the anatomy and function of the maxilla. The zygomaticomaxillary border stretches from the maxillary frontal process along the inferior orbital ridge to the zygomatic process of the frontal bone. The pterygomaxillary border extends from the anterior alveolar ridge to the pterygoid plate of the sphenoid bone. The nasomaxillary border extends from the anterior maxillary alveolus along the piriformis aperture to the nasal process of the maxilla (Figure 2) [2, 10].

Figure 1. Horizontal and vertical support walls [11].

Figure 2. Vertical support wall. Nasomaxillary border (NMB), zygomaticomaxillary border (ZMB), and pterigomaxillary border (PMB) [2].

The muscles that control facial expressions are located in the midline and are covered by facial skin. The outer surface of the face is divided into the cheeks, nose, and lips. All of these units have different characteristics and require special attention during reconstruction. The parotid glands are another important structure on the medial surface and are located in the most lateral region. These glands do not only function as salivary glands but also provide soft tissue for facial contours [10].

The mid-facial blood supply primarily originates from the branch of the external carotid artery. The anastomosis of this artery, such as branching of the infraorbital artery and internal maxillary artery, provides good vascularization to the skin. This pattern of anastomosis branching is very important in the management of mid-facial reconstruction. Mid-facial innervation is provided by cranial nerves, namely, the facial and trigeminal nerves. The facial nerve is responsible for facial movements, and the trigeminal nerve is responsible for the mastication muscle. Sensory innervation of the facial muscles is supplied by the branches of the trigeminal nerve [10].

Facial skin and soft tissue receive arterial supplies from branches of the facial temporal artery, maxilla, and all branches of the external carotid artery. Blood supply to the forehead, eyelids, and upper part of the nose is supplied through the internal carotid system by the ophthalmic artery. Blood supply to the lip region is supplied by inferior and superior labial arteries. The facial artery near the medial canthus next to the nose is the angular artery. The maxillary artery is the terminal branch of the external carotid artery with three main branches: the mental, buccal, and infraorbital arteries. The mental artery is the terminal branch of the inferior alveolar artery that passes through the mental foramen to supply the chin and lower lip. The buccal artery crosses the buccinator muscle to supply the cheek tissue [12].

The infraorbital arteries reach the face through the infraorbital foramen and supply the eyelids, cheeks, and lower nose. The deep temporal artery is the terminal branch of the

external carotid artery and crosses the superficial zygomatic arch in the superficial temporal fascia. The deep temporal artery is divided into anterior and posterior branches at 2 cm above the zygomatic arch. The anterior branch supplies the forehead and forms anastomosis with supraorbital and supratrochlear vessels, whereas the posterior branch supplies the parietal scalp and periosteum. The ophthalmic artery is a branch of the internal carotid system; its branches include the lacrimal, supraorbital, supratrochlear, infratrochlear, and external nasal arteries (Figure 3) [12].

Figure 3. Scheme of facial arteries [12].

FACIAL FAT COMPARTMENTS

Superficial Fat Tissue

The face has several compartments. Each compartment is separated by a network of fine fascia that forms a retaining ligament. The superficial facial fat layer consists of (1) the labial nasal fat compartment; (2) medial, middle, and lateral temporozygomatic fat pads; (3) medial, middle, and lateral temporozygomatic fat pads on the forehead; and (4) superior, inferior, and lateral orbital fat pads [12].

Nasolabial fat is located in the medial cheek adipose compartment and contributes to the nasolabial fold. The orbicularis retaining ligament below the inferior orbital plate borders the superior border of the nasolabial fat compartment and the medial cheek compartment. The middle fat compartment is limited by a group of fascia called the superior zygomatic septum on the superior side. The anterior border of the lateral temporal fat pads is the lateral zygomatic septum, which can be found during a facelift procedure with a dissection medial to the preauricular incision. The superior and inferior orbital fat compartments are located

within the boundary of the orbicularis retaining ligaments located above and below the eye. These periorbital fat pads are separated from each other by the medial and lateral canthus. The lateral orbital fat compartment has two borders: the superior border, which is the inferior temporal septum, and the inferior border, which is the superior zygomatic septum. The main zygomatic muscle is attached to the superficial fat compartment [12].

The anatomy of the superficial subcutaneous fat compartment has an impact on the facial contour. Differences in the volume at each level will cause deviations in the facial contour and loss of facial concavity [12].

Deep Fat Compartment

The suborbicularis oculi fat has two parts: the medial and lateral parts. The medial component is located along the margins of the inferior orbit, from the medial limbus towards the lateral canthus. The lateral component runs from the lateral canthus to the temporal fat pad. The prezygomal space lies between the suborbicularis oculi fat and the zygomatic periosteum. This space has superior borders, which are the orbicularis retaining ligament and the zygomatic retaining ligament. The sublevator fat pad is located medially from the medial suborbicularis fat compartment and is the deepest infraorbital pad. This fat pad is a continuation of the buccal fat pad. The buccal fat pad is an important structure located in the posterolateral part of the superficial maxilla towards the buccinator muscle and extends deep into the anterior part of the masseter muscle. Functionally, the buccal fat pad facilitates the movement of masticatory muscles (Figures 4-7) [12].

FIBROUS DYSPLASIA

Fibrous dysplasia is an asymptomatic disease. The disease occurs in the maxilla more often than in the mandible. In the maxilla, fibrous dysplasia manifests with edema, no pain, and is sometimes followed by café-au-lait spots. The mass may be large enough to interfere with the chewing function. In the mandible, swelling can involve the labial, buccal, and lingual areas [6, 13].

Extensive maxillary lesions can involve the maxillary sinus, zygomatic bone, sphenoid bone, and orbital base. Unstable swelling that continues to increase for a long time can result in an asymmetrical face shape. Nasal obstruction can occur when the paranasal sinuses are involved. In some cases, exophthalmus and tooth dislocation can occur because of malocclusion. Lesions that extend to the temporal bone can cause hearing loss [13–15].

Fibrous dysplasia lesion is a fibro-osseous lesion. These types of lesions have three variants: monostotic, polystotic, and McCune–Albright syndromes, which are associated with endocrinopathy and hyperpigmentation. Fibrous dysplasia occurs from the mutation of the guanine nucleotide-binding protein alpha-stimulating activity polypeptide 1 (GNAS-1) gene. Proteoblasts are formed because of proliferation and differentiation triggered by c-AMP. The GNAS-1 mutation results in encoding of the α -subunit during transduction of the G-protein signal, which results in the increase of c-AMP production [16, 17].

The severity of the disease depends on when the gene mutation occurred during pregnancy or after birth. If the mutation occurred during the embryonic phase, the osteoblasts, melanocytes, and endocrine cells will carry the gene mutations and express the genes in the form of multiple bone lesions and pigmentation accompanied by endocrine disorders, leading

to the McCune–Albright syndrome. Cells that mutate at the end of the embryonic phase will spread and fuse with bone to form multiple bone lesions, resulting in polystotic type fibrous dysplasia. Gene mutations that occur after birth will result in progenitor cell mutations that attach to one bone, resulting in monostotic type fibrous dysplasia [17,18].

FACIAL INCISION APPROACH

Surgical treatment for maxillectomy requires facial incisions to expose the maxillary bone. The type of incision depends on the tumor location, histology, and the surgeon's experience. Open surgery achieves good exposure of the tumor location, particularly for extensive resection [19].

Open surgery can be performed with various approaches. Five types of incisions can be employed to expose the maxilla: lateral rhinotomy incision, Weber–Ferguson incision, Weber–Ferguson incision with Lynch expansion, Weber–Ferguson incision with lateral expansion, and Weber–Ferguson incision with subciliary expansion [19].

Figure 8. Facial incision scheme. (A) Lateral rhinotomy incision, (B) Weber–Ferguson incision, (C) Weber–Ferguson incision with Lynch expansion, (D) Weber–Ferguson incision with lateral expansion, and (E) Weber–Ferguson incision with subciliary expansion [19].

Lateral rhinotomy is a basic incision that can be performed on the lesion without the involvement of the orbit or palate. The incision starts from the middle of the dorsum nasi to the medial canthus. The incision is performed following the shape of the face along the lateral

edge of the nose to the ala nasi. The Weber–Ferguson incision is performed by continuing the incision in the ala nasi, curving through the nasal vestibule and then continuing with the upper lip edge incision on the philtrum from the nasolabial gap to the vermilion border followed by an incision in the gingivobuccal. After the incision is made and the facial bones are exposed, osteotomy is performed according to the location and size of the tumor. The approach requires calculation of the position of the nasal pyramid as an aesthetic consideration. A tumor that involves the entire nasal cavity and maxillary sinus with posterior sinus wall erosion can be treated using Weber–Ferguson's incision, which enables maximal exposure of the tumor [19, 20].

The Weber–Ferguson incision with Lynch expansion is performed by extending the incision in the middle of the medial canthus towards the lower border of the eyebrows. The aim is to expand the exposure to the ethmoid cells, frontal sinuses, nasolacrimal ducts, and medial canthus ligaments. The Weber–Ferguson incision with lateral expansion is performed by pulling an incision from the middle of the medial canthus to the lateral canthus through the skin folds of the inferior eyelid. The Weber–Ferguson incision with subciliary extension requires an incision just below the inferior eyelid cilia. The Weber–Ferguson incision with lateral and subciliary expansion have a same goals to expanding the exposure of the infraorbital rim and the zygoma (Figure 8) [19].

MAXILLECTOMY

The maxillectomy procedure was first performed in 1820 and was first documented by Liston in 1841 in patients with nasopharyngeal angiofibroma. The aim of this surgical technique is to manage tumors in the nasal cavity, the lateral wall of the nose, and the maxillary sinus by removing the maxillary sinus bone [21, 22].

Several types of maxillectomy have been identified. Based on the writing by Hanna [22], the long-known types of maxillectomy are medial maxillectomy, inferior maxillectomy, superior maxillectomy, subtotal maxillectomy, and total maxillectomy.

Medial maxillectomy involves removing the lateral nasal wall and the medial segment of the maxillary bone, which is bordered by the infraorbital nerve on the lateral side accompanied by a sphenoetmoidectomy. Intracellular maxillectomy is a procedure that involves inferior resection of the maxilla under the infraorbital nerve plane. This technique is most commonly used for tumors in the maxillary alveolar process with minimal extension to the maxillary antrum and hard palate lesions. The combination of sublabial and palatal incisions is used to expose the maxilla followed by osteotomy. Mid-facial degloving can be used for lesions that cross in the midline and bilaterally involve the inferior maxilla [22].

Suprastructure maxillectomy is a procedure performed by maintaining the structure of the hard palate while resecting the floor of the orbit and the upper part of the maxilla. This procedure requires reconstruction of the orbital floor so that the eyeball does not fall towards the maxilla. Subtotal maxillectomy is a variation of maxillary resection in which the resection is carried out depending on the location of the tumor. Total maxillectomy involves resection of the entire maxilla, orbital floor, and palate (Figures 9-11) [22].

Spiro et al. [23] reported another maxillectomy classification based on a study of 403 patients who fulfilled one of the three criteria for maxillectomy. These criteria were related to

the number of maxillary walls resected and can be defined as limited, subtotal, and total maxillectomy.

Limited maxillectomy refers to all types of maxillectomy involving resection of only a maxillary wall in the antrum, usually the medial wall or maxillary base. Subtotal maxillectomy is a procedure in which at least two maxillary walls are resected, including the maxillary antrum floor, but resection does not reach the posterior maxillary wall.

Figure 9. Scheme of medial maxillectomy [22].

Figure 10. Scheme of inferior maxillectomy [22].

Figure 11. Scheme osteotomy lines of total maxillectomy [22].

This procedure includes resection of the pterygoid plate, soft palate, contralateral maxilla, zygoma, and nasal complex. Total maxillectomy is the removal of the maxilla accompanied by an orbital exenteration [23].

POST-MAXILLECTOMY DEFECT

There are various classifications of post-maxillectomy defects proposed to describe the resulting damage. These classifications were developed to guide reconstruction and rehabilitation [21].

Bidra et al. [24] concluded that the classification of defects must meet surgical and prosthodontic needs, be simple, comprehensive, easy to use, and be able to guide clinicians regarding reconstruction and rehabilitation options. Post-maxillectomy defects are classified into six criteria: dental defects, oronasal or orantral defects, defects of the soft palate and surrounding tissue, defect expansion to the superoinferior area, defect expansion to the anteroposterior area, and defect expansion to the mediolateral area.
